ABSTRACT

The ability to integrate semantic information into the context of a sentence is essential for human communication. Several studies have shown that the predictability of a final keyword based on the sentence context influences semantic integration on the behavioral, neurophysiological, and neural level. However, the architecture of the underlying network interactions for semantic integration across the lifespan remains unclear. In this study, 32 healthy participants (30–75 years) performed an auditory cloze probability task during functional magnetic resonance imaging (fMRI), requiring lexical decisions on the sentence's final words. Semantic integration demands were implicitly modulated by presenting sentences with expected, unexpected, anomalous, or pseudoword endings. To elucidate network interactions supporting semantic integration, we combined univariate task-based fMRI analyses with seed-based connectivity and between-network connectivity analyses. Behavioral data revealed typical semantic integration effects, with increased integration demands being associated with longer response latencies and reduced accuracy. Univariate results demonstrated increased left frontal and temporal brain activity for sentences with higher integration demands. Between-network interactions highlighted the role of task-positive and default mode networks for sentence processing with increased semantic integration demands. Furthermore, increasing integration demands led to a higher number of behaviorally relevant network interactions, suggesting that the increased between-network coupling becomes more relevant for successful task performance as integration demands increase. Our findings elucidate the complex network interactions underlying semantic integration across the aging continuum. Stronger interactions between various task-positive and default mode networks correlated with more efficient processing of sentences with increased semantic integration demands. These results may inform future studies with healthy old and clinical populations.

1 | Introduction

Efficient language comprehension in everyday communication requires the integration of context-dependent information into sentence meaning, a process known as semantic integration. There is consensus that the combination of words into a sentence generates expectations about further information (e.g., Kutas and Hillyard 1980), and the human brain constantly generates

context-dependent predictions about the subsequent input (for a review, see Ryskin and Nieuwland 2023). Numerous studies have shown that the integration of a final keyword into a sentence is influenced by the preceding context (e.g., Hagoort 2006; Hagoort and Indefrey 2014; Obleser and Kotz 2010; Rogalsky and Hickok 2009; Zhu et al. 2013). However, expectations about subsequent input are frequently violated in everyday communication, for example, when the less dominant meaning of an ambiguous word is processed or when we perceive jokes or ironic statements. Such situations require additional integration processes during lexical access (Franzmeier, Hutton, and Ferstl 2012).

At the behavioral level, higher semantic integration demands are reflected in increased response latencies and error rates (e.g., Baumgaertner, Weiller, and Büchel 2002; Kutas and Federmeier 2000; Kutas and Hillyard 1980; Lau, Phillips, and Poeppel 2008). At the neurophysiological or neural level, integration demands result in increased N400 amplitudes (DeLong, Quante, and Kutas 2014; Federmeier 2007; Kutas and Federmeier 2000; Kutas and Hillyard 1980; Lau, Phillips, and Poeppel 2008) and increased task-related activity in frontal and temporal brain areas (Baumgaertner, Weiller, and Büchel 2002; Hartwigsen et al. 2017). Previous neuroimaging studies investigating semantic integration in sentence endings with different levels of expectancy (cloze probability) showed increased activity in key areas of the semantic network, including the left anterior inferior frontal gyrus (aIFG), posterior superior temporal sulcus/middle temporal gyrus (pSTS/MTG), and anterior superior temporal sulcus/MTG (aSTS/MTG) for sentence endings with high integration demands, such as unexpected and anomalous endings (Baumgaertner, Weiller, and Büchel 2002; Hartwigsen et al. 2017).

To elucidate the mechanisms underlying semantic integration, it is essential to briefly explore the field of semantic cognition research. In the current literature, semantic cognition is typically defined as the effective use of acquired knowledge about the world (Badre and Wagner 2002; Hoffman, McClelland, and Lambon Ralph 2018; Jefferies 2013; Lambon Ralph et al. 2017). A growing body of evidence suggests that successful semantic cognition is based on two interacting components (Jefferies 2013; Lambon Ralph et al. 2017): (1) Semantic knowledge representation refers to the ability to store information about the meaning of objects, concepts, and words. (2) Semantic control processes regulate how aspects of our knowledge are retrieved and used in a specific context or during a specific task (Hoffman, McClelland, and Lambon Ralph 2018; Yee and Thompson-Schill 2016). All semantic tasks require the interaction of knowledge and control processes, although the weighting between both components may vary depending on the task. Moreover, studies investigating semantic cognition in the lesioned (e.g., Jefferies and Lambon Ralph 2006) or aging brain (e.g., Hoffman 2018; Hoffman and MacPherson 2022) suggest that both aspects can be impaired independently and rely on different neural systems. For example, older people generally show well-preserved semantic knowledge, whereas semantic control processes deteriorate with age (Grady 2012; Hoffman 2018; Hoffman and MacPherson 2022; Martin, Saur, and Hartwigsen 2022; Martin et al. 2023; Morcom and Johnson 2015; Wu and Hoffman 2022). At the neural level, several studies have shown that the anterior temporal lobes

(ATLs) function as a store of conceptual representations and are largely responsible for semantic knowledge through interaction with modality-specific association regions (Hoffman et al. 2017; Humphreys et al. 2015; Mion et al. 2010; Patterson, Nestor, and Rogers 2007; Pobric, Jefferies, and Ralph 2007). The controlled use of semantic knowledge, on the other hand, is primarily associated with the activation of a neural network that includes the inferior frontal gyrus (IFG), the posterior middle temporal gyrus (pMTG), and inferior parietal regions including the intraparietal sulcus (Noonan et al. 2013; Rodd, Davis, and Johnsrude 2005; Thompson-Schill et al. 1997).

Since these brain regions align well with the above discussed regions involved in semantic integration under increasing demands, this leads to the assumption that higher semantic integration demands require enhanced control processes within the semantic network. Several studies have investigated network connectivity during the performance of semantic tasks using fMRI (e.g., Davey et al. 2016; Jackson et al. 2016) or MEG (e.g., Kielar et al. 2016). However, it is less clear how exactly brain areas interact during semantic integration. Hartwigsen et al. (2017) explored task-related effective connectivity during semantic integration between preselected areas of the semantic network. This study revealed task-specific interactions between temporal and frontal areas: Relative to sentences with expected endings, sentences with unexpected endings increased the inhibitory influence of the left aSTS/MTG on left pSTS/MTG. In contrast, processing sentences with semantically anomalous endings required increased inhibitory connectivity from left aIFG to left pSTS/MTG. These results are supported by other studies that complemented task-related interactions during semantic processing with resting state connectivity (e.g., Jackson et al. 2016; Mascali et al. 2018). For example, Wawrzyniak et al. (2017) revealed a strong interaction between predefined areas in the left IFG, aMTG, and pMTG, and a left-dominant frontotemporal network of semantic language regions at rest. Increased functional connectivity between IFG and pMTG correlated positively with task performance under high semantic integration demands in the task paradigm. These results emphasize the relevance of interactions between the left IFG and pMTG in semantic control processes.

Previous research has shown that, in addition to a functionally specialized core network, domain-general networks are also crucial for successful language processing (e.g., Fedorenko and Thompson-Schill 2014). Indeed, tasks with high semantic control demands led to increased activation in areas that partially overlap with the multiple demand network (MDN)—a network activated in response to increased executive control demands across various cognitive domains, which includes brain regions in the prefrontal and parietal cortex as well as the pre-supplementary motor area and adjacent dorsal anterior cingulate (preSMA/ACC) (Duncan 2010; Fedorenko, Duncan, and Kanwisher 2013). FMRI studies suggest that semantic control can be divided into semantic-specific and domain-general components that activate adjacent brain regions in the left inferior prefrontal cortex (Badre et al. 2005; Hoffman 2018; Nagel et al. 2008). Controlled retrieval appears to be semantic-specific, a mechanism that comes into play when automatic activation of semantic knowledge is insufficient, for example, when a less dominant or unexpected word meaning must be accessed

(Badre and Wagner 2007). This controlled retrieval is associated with increased activation in the anterior ventral part of the left inferior prefrontal cortex (Brodman Area 47 [BA47]) (Badre et al. 2005; Dobbins and Wagner 2005; Gold et al. 2006; Jackson et al. 2016; Krieger-Redwood et al. 2015). Studies of the structural and functional connectivity of BA47 support this hypothesis, that is, the region where semantic knowledge is stored (Jackson et al. 2016; Jung et al. 2017; Von Der Heide et al. 2013). In contrast, semantic selection between competing representations seems to be controlled more by a domain-general executive selection system (Hoffman 2018). Here, increased brain activation has been found primarily in the posterior part of the left inferior prefrontal cortex (BA 44/45) (Badre et al. 2005; Gold et al. 2006; Thompson-Schill et al. 1997). Therefore, the interaction between domain-specific semantic regions and domain-general networks likely contributes to semantic integration. As the previous study by Hartwigsen et al. has primarily focused on effective connectivity between pre-selected areas of the semantic network during semantic integration, it is unclear how varying semantic integration demands modulate functional connectivity between large-scale cognitive networks at the whole-brain level. The present study aims to address this gap. Specifically, we were interested in whole-brain interactions during the processing of sentences with unexpected and anomalous endings.

Using a previously established auditory semantic integration paradigm (Hartwigsen et al. 2017), we combined univariate task-related functional magnetic resonance imaging (fMRI) analyses with seed-based connectivity and between-network connectivity analyses. This allowed for a comprehensive characterization of semantic integration at the whole-brain level. We expected that semantic integration demands should modulate the task-specific interaction between frontal, temporal, and potentially parietal areas. More specifically, we hypothesized that processing sentences with increased semantic integration demands, that is, sentences with unexpected and anomalous endings, would lead to a stronger interaction between brain regions involved in semantic control in the frontal and temporal cortex. We assumed that while processing unexpected sentence endings requires the suppression of the expected word, semantic integration generally succeeds. In contrast, for anomalous sentence endings we hypothesized that, while lexical word retrieval should be possible, semantic integration would require restructuring attempts. Consequently, we expected to find an even more pronounced interaction with frontal control regions during the processing of anomalous sentence structures compared to unexpected ones. Additionally, we examined the processing of sentences with pseudoword endings, where neither lexical word retrieval nor semantic integration of the pseudoword into the sentence context should be feasible. Here, we also anticipated a significant interaction with control regions, even though this condition likely leads to less pronounced recruitment of the semantic system compared to sentences with real word endings. In addition to the increased interaction between regions of the semantic network, we hypothesized that the interaction with domain-general networks, particularly during the processing of sentences with increased integration demands, is crucial. We expected that the interaction between task-positive networks increases as semantic integration demands rise. Conversely, we expected a stronger interaction with the default-mode network

during the more automated processing of predictable sentence endings. At the behavioral level, increased semantic integration demands should be reflected in increased response latencies and probably also decreased accuracy. Specifically, we expected an increase in response speed from expected to unexpected, anomalous and pseudoword endings. Furthermore, we assumed that behavioral performance might benefit from a stronger coupling between task-positive networks and a decreased coupling with task-negative networks such as the default mode network.

2 | Methods

2.1 | Participants

Thirty-three healthy participants were recruited via postings at the University Hospital Halle (Saale) and the database of the Max Planck Institute for Human Cognitive and Brain Sciences in Leipzig. One participant was excluded because of left-handedness. The final sample included 32 participants (mean age: 55.7 years, SD: 13.2, range: 30–75 years, 15 females). For a visualization of the age distribution, see Figure S1. On average, the participants had 16 years of education (SD: 2.4). All participants were native German speakers and, according to the Edinburgh Handedness Inventory (Oldfield 1971), right-handed (mean LQ: 91.5, SD: 9.0). They had normal hearing, normal or corrected-to-normal vision, and no history of neurological or psychiatric conditions or contraindications to magnetic resonance imaging (MRI). The study was approved by the local ethics committee of the University of Halle (Saale) and conducted in accordance with the Declaration of Helsinki. Participants gave written informed consent prior to the experiment. They received 10 Euro per hour for participation.

2.2 | Neuropsychological Assessment

To assess cognitive functioning, all participants performed a comprehensive neuropsychological test battery. They were screened for cognitive impairments using the Mini Mental State Examination (MMSE; Folstein, Folstein, and McHugh 1975; all $\geq 26/30$ points) and for depression with the Beck Depression Inventory (BDI-II; Beck et al. 1996; all ≤ 13 points). Furthermore, participants performed the Digit Span Test (Wechsler and De Lemos 1981) to assess their working memory capacity. The participants also underwent the subtests Alertness, Go/No-go 1 of 2, and Go/No-go 2 of 5 of the Test of Attentional Performance (TAP; Zimmermann and Fimm 2002). This battery evaluates different aspects of attention, including vigilance, response inhibition, and sustained attention. Demographic data and neuropsychological test results are shown in Table S1.

2.3 | Experimental Design and Stimuli

Our study employed an auditory cloze probability paradigm as previously described (Hartwigsen et al. 2017). This paradigm allows for modulating the demands of semantic integration by varying the predictability of the last word in a sentence across four different experimental conditions. The final word can either be (1) expected (e.g., "The pilot flies the *plane*."), (2) unexpected (e.g.,

“The pilot flies the *kite*.”, or (3) semantically anomalous (e.g., “The pilot flies the *book*.”). Additionally, pseudoword endings (e.g., “The pilot flies the *kirst*.”), make successful semantic integration impossible. Participants had to perform a lexical decision task (word or a pseudoword) on the sentence's final words. Stimuli consisted of 60 sentences for each word condition (expected, unexpected, anomalous words), and 120 sentences for the pseudoword condition (i.e., 60% word endings vs. 40% pseudoword endings, 300 sentences in total). To ensure that the context matched between the four conditions, the same sentence stems (subject + verb phrase) were used, with only the last word (object phrase) being varied accordingly. In addition to the 300 experimental trials, a separate set of 50 practice sentences was used for training outside of the scanner. All sentences were recorded by a female, professional German speaker. For details regarding stimulus creation, please refer to Hartwigsen et al. (2017).

2.4 | Experimental Procedure

The data were collected in a single session of 3 h for each participant. After the participants provided informed consent, they completed the neuropsychological assessment, followed by a short training of the experimental task outside the scanner. The subsequent MRI measurement lasted about 1 h and included the acquisition of a T1-weighted anatomical dataset as well as several fMRI scans (resting state, semantic integration paradigm, language localizer, breath hold task). Here, we focus on the results of the semantic integration task, as the other measures were performed to collect control data in the context of an ongoing patient study. The semantic integration task was implemented in two event-related fMRI runs and had a total duration of 27 min. During the experiment, participants looked at a black screen with a white fixation cross in the center. All 300 stimuli were presented auditorily via MR-compatible over-ear headphones. Sentence duration ranged from 1.5 to 2.6 s, with a jittered inter-trial interval of 1.5–4.4 s. Both runs contained the same number of stimuli for each condition (30 expected, 30 unexpected, 30 anomalous, 60 pseudowords). The distribution and order of stimuli across both runs were generated for each participant individually as a pseudo-randomized list, ensuring that a maximum of three sentences from the same condition could occur consecutively. Subjects performed a lexical decision task (Is the last word a real word or a pseudoword?) by

responding via button press with their left middle (pseudoword) or index finger (word), and reaction times and accuracy data were collected. Note that the left hand was used to avoid button-press related left-hemispheric motor activity. Presentation of the stimuli and triggering of the scanner was conducted through PsychoPy (Peirce et al. 2019). For a visualization of the experimental design see Figure 1.

2.5 | Data Acquisition and Preprocessing

Functional imaging was performed on a human whole body 3-Tesla scanner (Magnetom Skyra, Siemens, Erlangen, Germany) equipped with a 32-channel head coil. For the acquisition of fMRI data during the semantic integration task, a gradient echo-planar imaging (EPI) sequence was used (TR/TE = 2.24 s/0.03 s, flip angle 90°, field of view (FOV): 100 mm, matrix: 76 × 76 pixel, voxel size: 3 × 3 × 3 mm). A total of 360 image stacks consisting of 40 transversal slices each were acquired continuously during each session. Additionally, T1-weighted anatomical images were acquired with an MPRAGE sequence in sagittal orientation (voxel size = 1 × 1 × 1 mm; TR = 2.53 s; TE = 0.00267 s). Preprocessing was performed using fMRIPrep 23.0.0 (Esteban et al. 2019), which is based on Nipype 1.8.7 (Gorgolewski et al. 2011). In summary, preprocessing comprised skull stripping, co-registration, slice timing correction, and calculation of several confounding time-series for each of the two functional runs per participant. Anatomical T1-weighted images were skull-stripped, segmented, and spatially normalized to the MNI152NLin6Asym template. For details on the preprocessing pipeline, see Note S1 and fMRIPrep's documentation (https://fmriprep.org/en/23.0.0/workflows.html). Finally, functional images were smoothed with a 6 mm FWHM Gaussian kernel using SPM12 implemented in MATLAB R2022b (9.13; The Mathworks Inc., Natick, MA, USA).

2.6 | Behavioral Data Analysis

The statistical analysis of reaction times and error rates was conducted using R 4.2.2 via RStudio (R Core Team 2021). We utilized the packages lme4 (Bates et al. 2014) and ggeffects (Lüdecke 2018) for mixed models and ggplot2 (Wickham 2016)

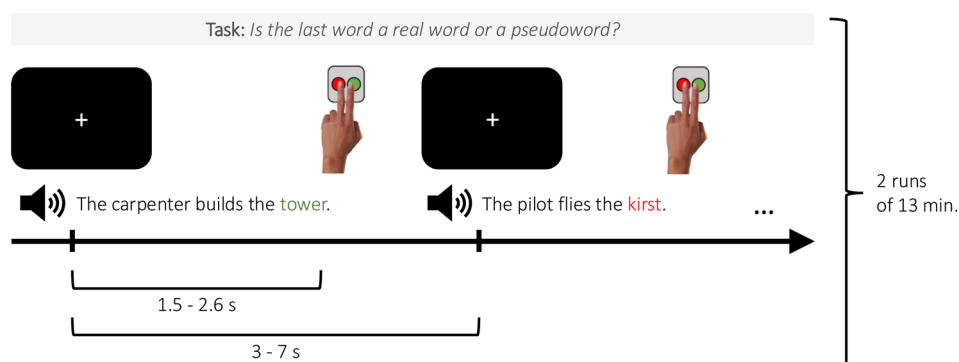

FIGURE 1 | Experimental design of the semantic integration task. The figure illustrates two fMRI trials. Sentences were presented in an event-related fashion with a variable stimulus onset asynchrony between 3 and 7 s. Sentence duration varied between 1.5 and 2.6 s. After the auditory presentation of the sentence, subjects had to indicate via button press whether the final word represented a word or pseudoword (lexical decision). Reaction times (from the last word onset) and error rates were measured.

for visualizations. Reaction times were measured from the onset of the last word in a sentence to the button press. Incorrect responses, omissions, and trials in which the button was pressed before the onset of the last word were excluded from the analysis of reaction times. Reaction times were corrected for outliers (based on the individual means by subject and condition +/− 2 SDs). For the analysis of reaction time data (Equation S1), a linear mixed-effects model with the log-transformed data was computed. As fixed effects, we included condition, age, and their interaction term. Intercepts for participants and stimuli were defined as random effects. Additionally, we entered education as a covariate of no interest to account for a potential effect on performance in the semantic integration task. p values were calculated using likelihood ratio tests comparing the full model with the effect in question against the model without the effect in question. The emmeans package (Lenth 2020) was applied for post hoc comparisons, using Bonferroni–Holm correction. For the analysis of error rates, a generalized linear mixed-effects logistic regression was used to account for the binary nature of the response variable (Equation S2). However, since the model including an interaction of condition and age failed to converge, we defined the model without this interaction.

We used deviation (simple) coding for our categorical predictor "condition." The purpose of simple coding is to create numeric variables that capture deviations from the overall mean of a continuous variable or the baseline level in case of categorical variables, thereby allowing for comparisons in terms of deviations from a central reference point across different levels of a variable. The numeric variables "education" and "age" were mean-centered and scaled to have unit variance.

2.7 | Univariate fMRI Analysis

For the statistical analysis of fMRI data, a two-level approach was implemented using SPM12. On the first level, a general linear model (GLM) with a flexible factorial design was created for each participant. Each run was modeled separately in this design. The GLM included regressors for the onsets and durations of the four stimulus conditions, as well as a regressor of no interest for incorrect trials (wrong button presses). Nuisance regressors, consisting of the six motion parameters and individual regressors for strong volume-to-volume movement, as indicated by framewise displacement (FD) values > 0.9, were also defined. Additionally, age was included as a covariate in the model. A high-pass filter with a cut-off of 128 s was applied to the data before model estimation. Statistical parametric maps of the t-statistic were generated by estimating the contrast of each condition against rest and the direct contrasts between the individual conditions. Additionally, the contrasts "sentences with word endings > sentences with pseudoword endings" and "sentences with pseudoword endings > sentences with word endings" were estimated by combining the trials of the three word-conditions.

For the second-level analysis, the contrast images of the pooled parameter estimates were entered into a random effects model. A one-sample t-test was performed for within-group comparisons. Contrasts were thresholded at $p < 0.05$ and corrected for multiple comparisons using the family-wise error method at the cluster level (FWEc). The SPM anatomy toolbox (version 3.0; Eickhoff et al. 2005) was used for the anatomical localization of activation peaks.

2.8 | Functional Connectivity Analysis

2.8.1 | Generalized Psychophysiological Interaction Analyses

To investigate task-related changes in functional connectivity during semantic integration, we conducted a generalized psychophysiological interaction (gPPI) analysis using the gPPI toolbox for SPM12 (version 13.1; McLaren et al. 2012). Since we were mainly interested in the functional connectivity underlying challenging but successful semantic integration processes, we defined our seed regions for areas that showed greater activation for unexpected and anomalous sentence endings relative to expected sentence endings. To this end, we ran a conjunction analysis: "unexpected > expected ∩ anomalous > expected" (see Figure S2). Subsequently, seed regions were defined for all global maxima within this conjunction (FWEc, $p < 0.05$) (see Table S2). A spherical ROI with a radius of 10 mm was created around each peak coordinate, using the MarsBaR toolbox (version 0.45; Brett et al. 2002). Within this boundary, we searched for the top 25% active voxels (positive) in each participant and defined them as our subject-specific ROIs. All participants had active voxels within the spherical masks. Next, we conducted the standard two-level approach by performing a whole-brain random-effects group analysis based on the GLM. At the first level, individual participant data were modeled separately using the gPPI toolbox. The first level GLM included: (1) "Psychological" regressors for all four experimental conditions convolved with the canonical hemodynamic response function (HRF), (2) a "physiological" regressor consisting of the deconvolved time series of the first eigenvariate of the BOLD signal from the respective seed ROIs, (3) PPI regressors for each experimental condition, which were calculated by multiplying the deconvolved BOLD signal of the respective seed ROIs with the condition onsets and convolving with the canonical HRF (McLaren et al. 2012), (4) nuisance regressors, consisting of the six motion parameters and individual regressors for strong volume-to-volume movement, as indicated by FD values > 0.9. Resulting participant level contrast images were entered into t-tests on the group level. To test for functional coupling during semantic integration, we compared the connectivity for all our task contrasts by using paired t-tests. For all group-level analyses, a gray matter mask (SPM12 tissue probability map) was applied, restricting statistical tests to voxels with a gray matter probability > 0.3. All activation maps were thresholded at a voxel-wise $p < 0.001$ and a cluster-wise $p < 0.05$ FWE-corrected for multiple comparisons. We also tested the gPPI analysis using seed regions defined by the peak coordinates of the individual contrasts unexpected > expected and anomalous > expected (instead of the conjunction of both). However, no significant results were found for this approach.

2.8.2 | Independent Component Analysis

To further assess which large-scale networks are active during the semantic integration task, we conducted a groupwise

spatial independent component analysis (ICA; Calhoun, Liu, and Adalı 2009). ICA decomposes fMRI time series into multiple source components in a data-driven manner. While artifactual components can be removed (Griffanti et al. 2014), the remaining independent components (ICs) correspond to functionally connected neural networks.

The preprocessed, normalized, and smoothed data were analyzed using the Group ICA of fMRI Toolbox (GIFT v4.0c), which initially intensity-normalized the data before implementing the ICA. Data dimensions were reduced with a two-step expectation maximization principal component analysis (PCA) procedure. To this end, PCA was first performed at the run level, with dimensions being reduced from the full time-course-length (360 timepoints) to a participant-specific number of components as determined by the Minimum Description Length (MDL) criterion (Rissanen 1978). Second, data were concatenated to further reduce dimensionality on the group level, again using the MDL criterion to determine the number of ICs. The MDL approach allows for an adaptive determination of the optimal number of components based on the data characteristics, providing a more tailored analysis compared to a fixed number of components (Rissanen 1978; Schwartz 1978). ICA was implemented using the Infomax algorithm (Calhoun et al. 2002). To ensure the reliability of the decomposition, Icasso was repeated 50 times with a cluster size determined by the MDL-derived number of components (Himberg and Hyvarinen 2003). In the last step, the back-reconstruction of group-level ICs to the subject level was performed using the GICA3 algorithm in GIFT (Calhoun et al. 2001). For the remaining analyses, the components were scaled to *Z*-scores within each component. The resulting 36 ICs were visually inspected following the established criteria of Griffanti et al. (2014). After discarding components attributable to artifacts and noise, we identified a total of 11 network components. The spatial extent of these 11 components at the group level was determined using a one-sided t-test on the spatial maps of the participants. Results were corrected for multiple comparisons using a cluster-level threshold at $p < 0.05$ with the family-wise error (FWE) method.

2.8.3 | Brain Network Identification

To guide visual inspection in determining network labels for the 11 resulting component maps, we relied on the Jaccard similarity coefficient (*J*; Jaccard 1912). The Jaccard similarity coefficient computes spatial similarity in the form of overlapping voxels between two binary spatial network masks (i.e., a component map A and a template map B), compared to all other voxels in the brain. This spatial similarity measure results in values between 0 and 1, where 0 indicates no similarity, and 1 indicates a complete match. It should be noted that different definitions and naming conventions for neural networks currently coexist in the literature. We selected the template images from the 17-network functional connectivity-based parcellation scheme by Yeo et al. (2011), which is based on resting-state data and provides a well-established basis for functional parcellation of the brain, increasing the comparability and reproducibility of the results. However, this scheme does not include the MDN, a network we hypothesized to be relevant for semantic and domain general control. Instead, in the parcellation scheme of Yeo

et al. (2011), the typical regions of the MDN are mainly covered by the frontoparietal control networks (Co).

2.8.4 | Network Activity

To investigate the activity of networks during various conditions of the semantic integration task, we used the temporal sorting utility in GIFT. Multiple regression analyses were performed between the time courses of the selected components and the design matrix from the GLM at the subject level. Through this analysis step, beta values for each network and each condition were obtained per run, representing the activity of a network for a given task predictor (11 ICs × 4 conditions × 32 subjects × 2 runs).

Initially, we examined the FDR-corrected network activity for each individual task condition compared to the rest condition. We decided to retain only those networks that exhibited significant (de/) activation ($p < 0.05$) for at least one condition versus rest for further analysis. This resulted in a selection of seven networks and ensured that our subsequent analysis of differences in network activity between conditions focused only on networks that seemed to be task relevant.

To determine how the seven networks responded during individual conditions, pairwise comparisons of activity estimates for the respective conditions were conducted. Since this study focused on investigating semantic integration under challenging conditions, we were particularly interested in network activity during unexpected and anomalous compared to expected sentence endings. Additionally, we examined network activity for the two most opposing conditions: pseudoword endings (which cannot be semantically integrated into the overall meaning of the sentence) compared to expected sentence endings (which can be most easily integrated). To this end, the primary beta values for each network were initially averaged across runs. Subsequently, the utility in GIFT, "Stats on Beta Weights," was used to conduct paired t-tests on the subject level for the chosen conditions (unexpected vs. expected, anomalous vs. expected, pseudoword vs. expected). The results were FDR-corrected, and the significance threshold was set at $p < 0.05$.

2.8.5 | Network Interactions

To investigate task-related interactions between the seven networks that showed significant network activity in the task versus rest comparison, we applied a correlational psychophysiological interaction (cPPI) analysis (Fornito et al. 2012). CPPI computes pairwise partial correlations between ROIs and produces an output in the form of undirected, symmetrical connectivity matrices. To examine network interactions for the tasks reflecting increased semantic integration demands, we performed cPPI for the contrasts "sentences with unexpected vs. expected endings" and "sentences with anomalous vs. expected endings." Additionally, we were interested in contrasting sentences with semantically nonintegrable pseudoword endings and sentences with easily integrable, expected word endings.

During cPPI analyses, the deconvolved time series of each network were multiplied with the task time course from the design
FIGURE 2 | Behavioral results. Differences in reaction times (left panel) and error rates (right panel) between task conditions. *$p < 0.05$, Bonferroni–Holm corrected.

matrix of the first-level analysis and convolved with a canonical HRF to create a PPI term. Subsequently, pairwise partial correlations between the PPI terms and two networks were estimated, while controlling for all remaining regressors in the GLM, the noise regressors, and the activity of the 10 remaining networks. Task-specific network interactions were assessed by contrasting the above-mentioned conditions of interest. As a result, a symmetrical 7×7 connectivity matrix was obtained for each subject and contrast. Finally, the correlation coefficients were Fisher-transformed into z-values and the full matrices, including positive and negative correlation weights, were statistically tested at the group level. Interactions were considered significant at $p < 0.05$. Additionally, we used the Network-Based Statistic (NBS) Toolbox (Zalesky, Fornito, and Bullmore 2010) to investigate potential differences in the coupling of networks between the task contrasts. However, no significant results were found in this analysis.

2.8.6 | Behavioral Performance and Network Interactions

For the contrasts "unexpected vs. expected sentence endings," "anomalous vs. expected sentence endings," and "pseudoword vs. expected sentence endings," we investigated the effects of the interaction among networks on participants' reaction times and error rates by fitting linear mixed-effects models (Equations S3 and S4). Models included fixed effects for the corresponding mean-centered network measure, condition, their interaction term, age, education, and by-participant random intercepts.

Additionally, we investigated the performance of the participants in the neuropsychological tests with regard to a potential correlation with the connectivity values of the networks. For this purpose, a sum score from all neuropsychological test results was calculated for each participant. Subsequently, a correlation analysis between the sum scores and the connectivity values of the networks for the respective task contrasts was conducted.

However, after removing an outlier, no significant correlations were observed here.

3 | Results

3.1 | Semantic Integration Demands Are Reflected in Behavioral Responses

Analyses of reaction times revealed a significant two-way-interaction of condition and age ($\chi2 = 24.3249$, $p < 0.001$). Post hoc tests showed significant differences in reaction times between all three word conditions (all $p < 0.001$), with the shortest reaction times observed for sentences with expected endings, followed by sentences with unexpected and anomalous endings. The longest reaction times were measured for sentences with pseudoword endings. However, reaction times for anomalous versus pseudoword sentence endings did not differ significantly (Figure 2, left). For error rates, we found main effects of condition ($\chi2 = 71.793$, $p < 0.001$) and age ($\chi2 = 8.018$, $p < 0.001$). Post hoc tests revealed significant differences in error rates between all conditions (all $p < 0.001$), except for the contrast of unexpected vs. expected sentence endings ($p = 1.0$). The highest error rate was found for sentences with anomalous endings, followed by sentences with pseudoword endings and unexpected endings. The lowest error rate was observed for sentences with expected sentence endings (see Figure 2, right). Complete model outputs are reported in Table S3. Furthermore, both reaction times and error rates, particularly for conditions with increased semantic integration demands, showed an increase with advancing age (see Figure S3).

3.2 | Semantic Integration Demands Increase Task-Related Activity in Left Fronto-Temporal Areas

Our goal was to investigate the neural correlates underlying semantic integration under varying conditions. For all examined
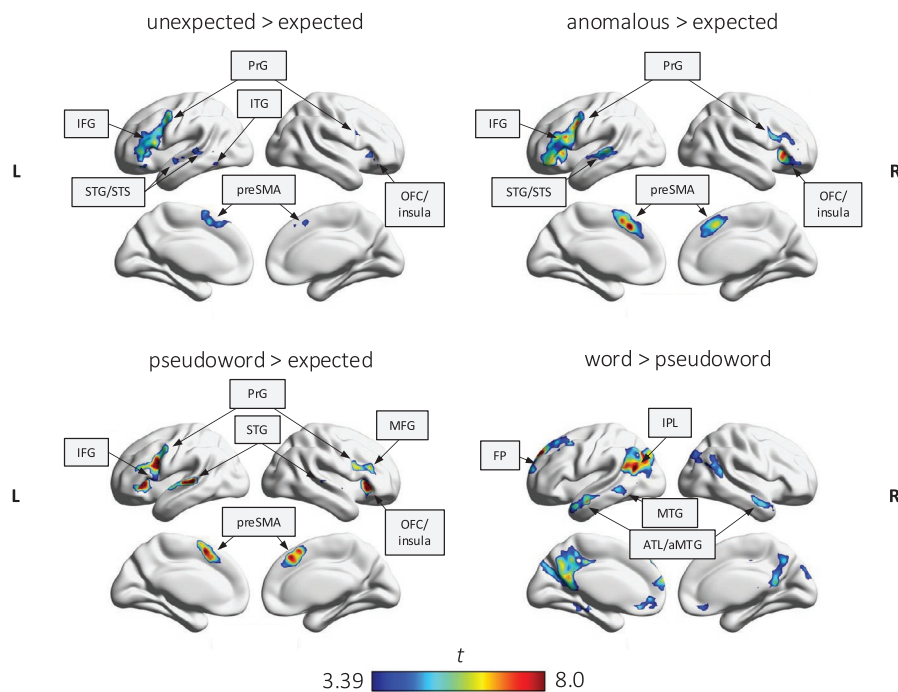

FIGURE 3 | FMRI results on the group level from the univariate analysis for our semantic contrasts of interest. Results are FWE-corrected at $p < 0.05$ at the cluster level. FIGURE 4 | Task-dependent changes in functional connectivity for seeds in the left inferior frontal gyrus (IFG) and the contrast unexpected sentence endings > expected sentence endings (left) as well as the presupplementary motor area (preSMA) and the contrast expected sentence endings > anomalous sentence endings (right). All results are FWE-corrected at $p < 0.05$ at cluster level.

contrasts, we observed the expected brain activation in a predominantly left-lateralized fronto-temporo-parietal language network (Figure 3 and Table S4).

Increased semantic integration demands were generally reflected by a frontal activation pattern. Specifically, the contrasts of unexpected, anomalous and pseudoword sentence endings versus expected sentence endings all showed activation in the IFG, the orbitofrontal cortex (OFC), and the preSMA. For the "unexpected sentence endings > expected sentence endings" contrast, additional activation was found in the right precentral gyrus (PrG), the right cerebellum (VI), and the left inferior temporal gyrus (ITG). A similar, although even more pronounced activation pattern emerged for the "anomalous sentence endings > expected sentence endings" contrast. Here we found additional brain activation in the right cerebellum (VI), the left superior temporal gyrus (STG) and the right cerebellum Crus II. Finally, for sentences with pseudoword endings compared to

expected endings we observed additional activation in the middle frontal gyrus (MFG).

In contrast, the processing of sentences with expected endings was associated with predominantly temporo-parietal brain activity. We also examined blood-oxygen-level-dependent (BOLD) signal differences during the processing of sentences with word endings (encompassing the conditions expected, unexpected, and anomalous) > sentences with pseudoword endings. We found the largest differences in brain activation in the left inferior parietal lobe (IPL), the left frontal pole (FP), the left middle temporal gyrus (MTG), the left parahippocampal gyrus, and the right MTG. Additional contrasts between the individual task conditions are included in Figure S4. No significant effect of age was found in our univariate analysis.

3.3 | Functional Connectivity Results

3.3.1 | Semantic Integration Demands Increase Task-Related Interactions Between Frontal and Subcortical Areas

We ran gPPI analyses for seeds derived from the conjunction of the tasks with increased semantic integration demand, that is, unexpected and anomalous sentence endings. Results revealed significant task-specific interactions for the seeds in the left IFG and preSMA. For unexpected > expected words, we found increased functional connectivity between left IFG and the thalamus (Figure 4, left). For the contrast expected > anomalous words, left preSMA showed increased coupling with the right cerebellum (Figure 4, right). We also performed gPPI analysis for regions with increased activation for individual contrasts of unexpected and anomalous conditions relative to expected words. Results did not indicate significant changes in functional connectivity for these seeds.

3.3.2 | Semantic Integration Is Characterized by Distributed Large-Scale Networks

We defined functional networks for the semantic integration task by performing spatial ICA at the group level. After filtering out noise components from a total of 36, we identified 11 network components encompassing 10 cortical components and one component in the cerebellum.

To assign the 11 ICs to cognitive networks, we calculated the Jaccard similarity coefficient between our binarized and thresholded ICs and template masks of neural networks from Yeo et al. (2011). With the exception of IC16 and IC33, all ICs showed a similarity coefficient above the threshold recommended by Jackson et al. (2019) ($J = 0.15$) for at least one network template. The Jaccard indices for individual ICs and network templates are listed in Table S5. IC16 exhibited predominantly cerebellar connectivity and was thus not represented in the cortical templates of Yeo et al. (2011). Consequently, we labeled IC16 as the cerebellum. For all other ICs, we chose the label according to the highest Jaccard similarity coefficient. We found two control networks: ContA (IC25, $J = 0.241$) and ContB (IC17, $J = 0.159$), two default mode networks: DefaultA (IC11, $J = 0.225$) and DefaultB

(IC35 = 0.273), as well as two somatomotor networks: SomMotA (IC12, $J = 0.274$) and SomMotB (IC04, $J = 0.288$). IC13 showed the highest similarity to the salience/ventral attention network A (SalVentAttnA, $J = 0.240$). IC18 showed the highest Jaccard similarity coefficient for the central visiual network (VisCent, $J = 0.197$). Two networks showed the highest agreement with the peripheral visiual network (IC21, $J = 0.286$; IC33, J = 0.122). Figure 5 shows the thresholded maps (FWE-corrected at the cluster level with $p < 0.05$) with their original component numbers. Please note that the figure only includes the selected non-noise components that showed significant (de/) activation for at least one task condition, since we decided to focus on those components in our further analysis. Details will be explained in the next paragraph.

3.3.3 | Semantic Integration Demands Differentially Modulate Network Activity

To focus subsequent analyses on networks relevant to the semantic integration task, we examined network activity for each task condition compared to rest. In total, seven of the 11 networks showed significant (de/) activation in at least one task condition (see Figure 6, top panel). A detailed summary of the beta and p values of all 11 networks can be found in Table S6. Both somatomotor networks (SomMotA and SomMotB) showed significant positive activation for all four task conditions. The two control networks revealed a more complex picture: While ContA showed significant positive network activity for the three conditions with increased integration demands (unexpected, anomalous and pseudoword), ContB was significantly deactivated for the sentences with unexpected word endings. The two default mode networks showed overall more deactivation, which was significant for all four conditions in the DefaultA network, but only for the pseudoword condition in the DefaultB network. Finally, the cerebellum showed positive network activity that reached significance for the anomalous condition. All other networks (IC13, IC18, IC21, IC33) showed no significant (de/) activation and were thus excluded from the following analysis.

Next, we examined the activity of the remaining seven networks during the semantic integration task for three contrasts reflecting increasing integration demands ("unexpected vs. expected sentence endings," "anomalous vs. expected sentence endings," and "pseudoword vs. expected sentence endings"). The differences in beta values between conditions are depicted in Figure 6 (bottom panel) and described in Table S6 for each network. No significant (de/) activation was found for the "unexpected vs. expected sentence endings" contrast. However, a significant positive activation of ContA was detected for the more challenging task contrasts "anomalous vs. expected sentence endings" and "pseudoword vs. expected sentence endings." Furthermore, DefaultA showed significant deactivation for "pseudoword vs. expected sentence endings."

3.3.4 | Semantic Integration Demands Mainly Increase Interactions Between Task-Positive Networks

To investigate how the seven ICA-derived networks interact with each other during different conditions of the semantic
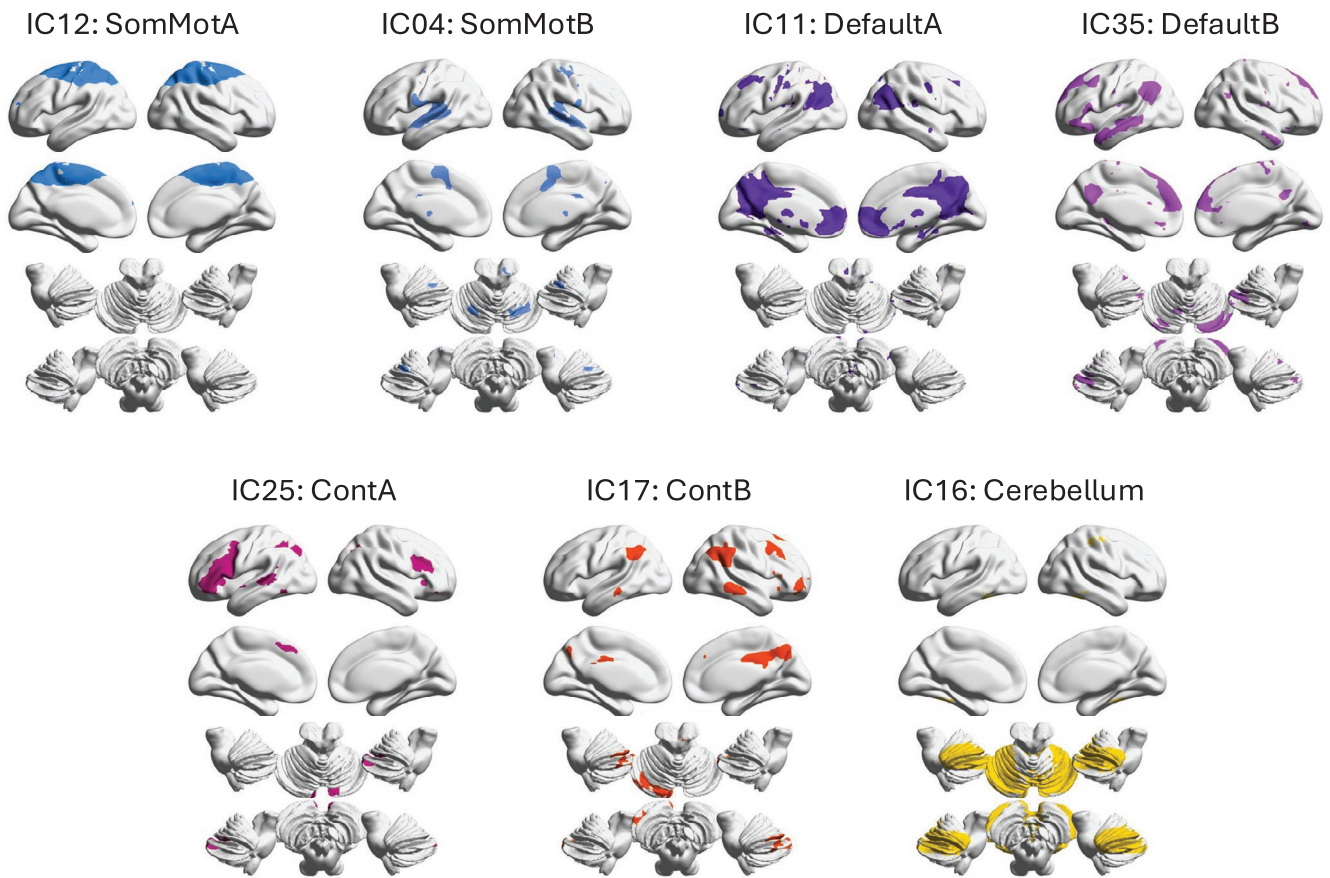

FIGURE 5 | Spatial ICA-derived networks during the semantic integration task. Networks are shown as binary masks, created from the *T*-scores from 1-sided *t*-tests (FWE-corrected $p < 0.05$ at cluster level). Network labels were chosen according to the spatial similarity analysis. ContA/B: Control network A/B; DefaultA/B: Default mode network A/B; SomMotA/B: Somatomotor network A/B.

integration task, a cPPI analysis was conducted, resulting in a 7×7 correlation matrix for each task contrast (Figure S5B). Significant network interactions for our contrasts of interest ("unexpected vs. expected sentence endings," "anomalous vs. expected sentence endings," and "pseudoword vs. expected sentence endings") are shown in Figure 7 (left column). Additional results are visualized in Figure S5A.

Networks typically classified as task-positive (ContA and ContB) as well as somatomotor networks predominantly exhibited increased positive interactions with one another across all three task contrasts. Conversely, these task-positive networks displayed increased negative interactions with default mode networks. Exceptions were the positive interactions between DefaultB and SomMotB, DefaultA and ContA, and DefaultA and ContB, the last pair only for the two semantic contrasts (unexpected vs. expected and anomalous vs. expected), but not for the contrast between pseudowords and expected sentence endings. Furthermore, we found a negative interaction between the two control networks ContA and ContB for all three task contrasts. The cerebellum showed a predominantly positive network modulation with SomMotA and ContB, and a weak negative interaction with ContA. Interestingly, however, this cerebellar interaction pattern differed for the anomalous versus expected contrast. In this case, an increased negative interaction with DefaultB was predominant, a pattern not observed in the other two contrasts. Furthermore, the results show that for the

two semantic contrasts (unexpected vs. expected and anomalous vs. expected), more network interactions reached statistical significance ($n = 18$) than for the contrast between pseudoword and expected endings ($n = 11$).

3.3.5 | Higher Integration Demands Result in an Increased Number of Behaviorally Relevant Network Interactions

Finally, we examined the behavioral relevance of these significant network interactions for the task contrasts "unexpected vs. expected sentence endings," "anomalous vs. expected sentence endings," and "pseudoword vs. expected sentence endings" (see Figure 7, right column; Tables S7–S9 for details). We did not detect any significant effect of network coupling on error rates. However, results revealed interactions between reaction times in the respective semantic conditions and network interactions. Remarkably, we found more behaviorally relevant network interactions for higher integration demands. For the "unexpected vs. expected sentence endings" contrast, we found a significant interaction between SomMotA and DefaultA. Increased coupling between these networks was associated with faster reaction times, especially for unexpected trials. For sentences with anomalous endings versus expected endings, significant network interactions were observed between SomMotB and ContA as well as SomMotB and
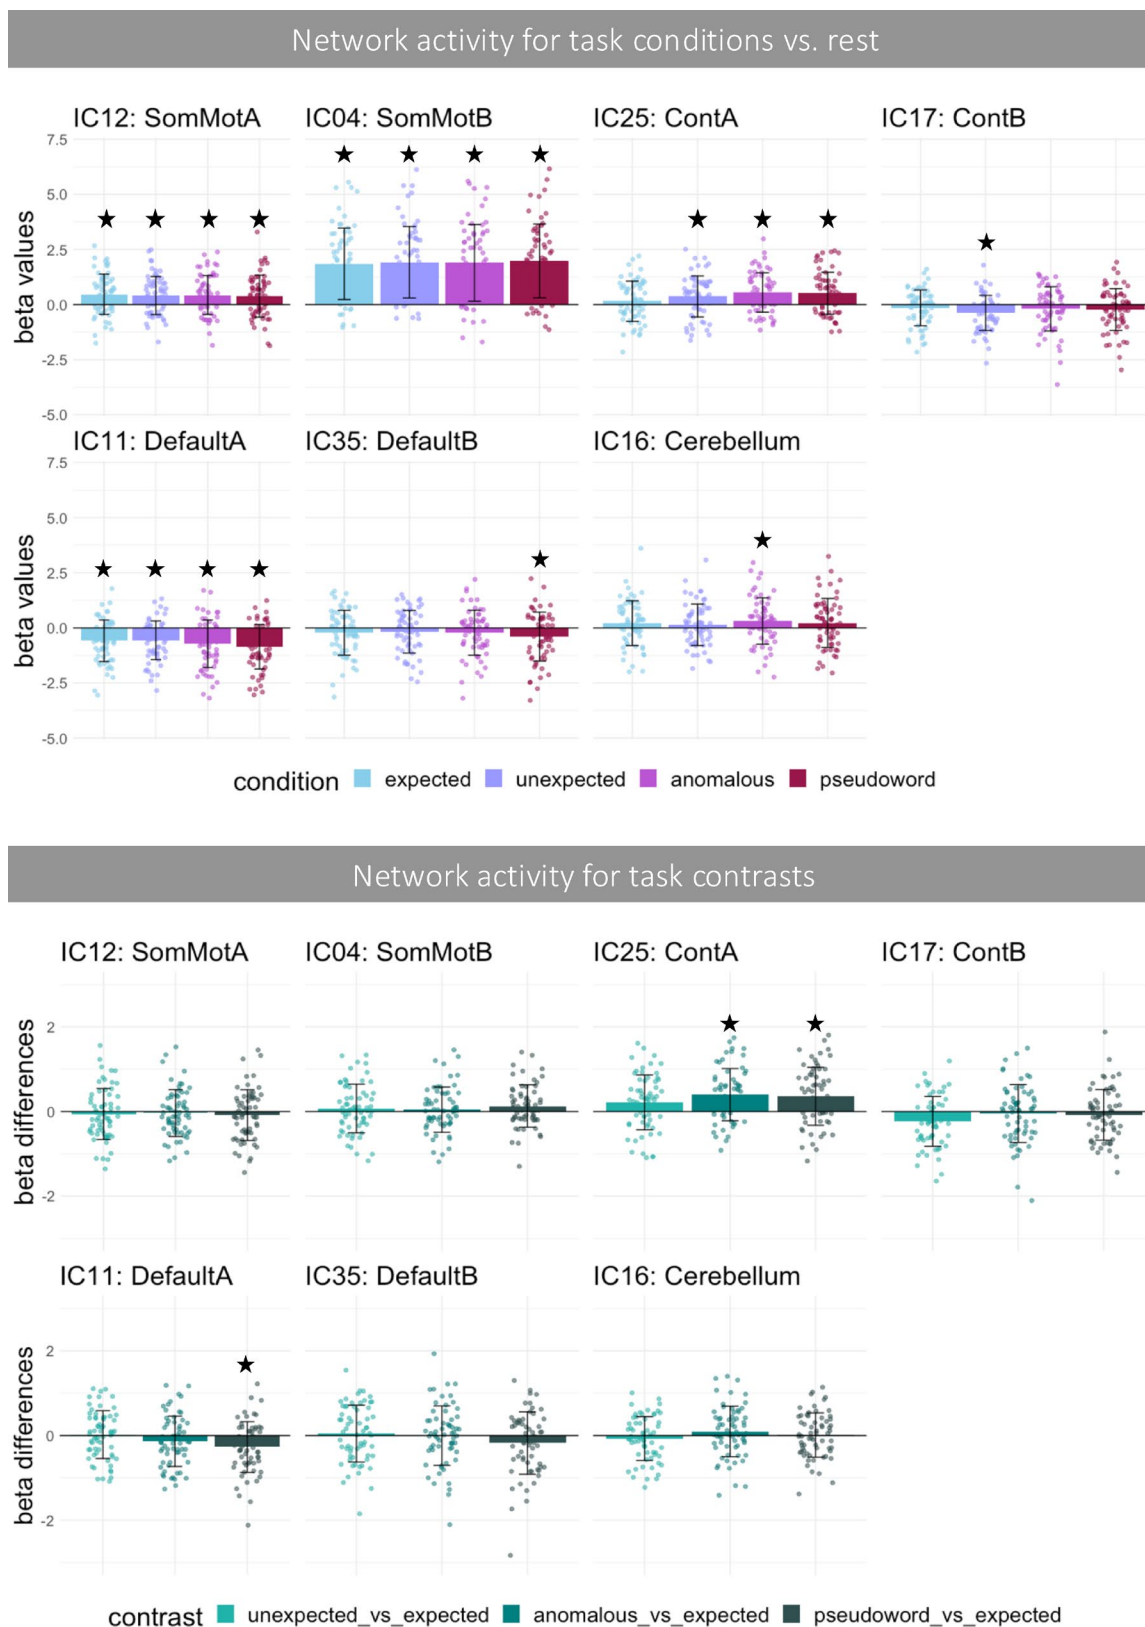

FIGURE 6 | Network activity during semantic integration. Top Panel: Network activity (beta weights ± SD) for the conditions expected, unexpected, anomalous and pseudoword compared to rest. Bottom Panel: Network activity calculated from differences between mean beta weights (±SD) for the contrasts of unexpected, anomalous and pseudoword versus expected trials. Asterisks indicate significance for a given network's contrast t-test (FDR-corrected, $p < 0.05$). ContA/B: Control network A/B; DefaultA/B: Default mode network A/B; SomMotA/B: Somatomotor network A/B.

DefaultB. While a stronger interaction between SomMotB and ContA was reflected in slower reaction times for anomalous trials, coupling led to faster reaction times in the expected condition. The interaction between SomMotB and DefaultB instead promoted faster reaction times for sentences with anomalous endings. Regarding reaction times for sentences

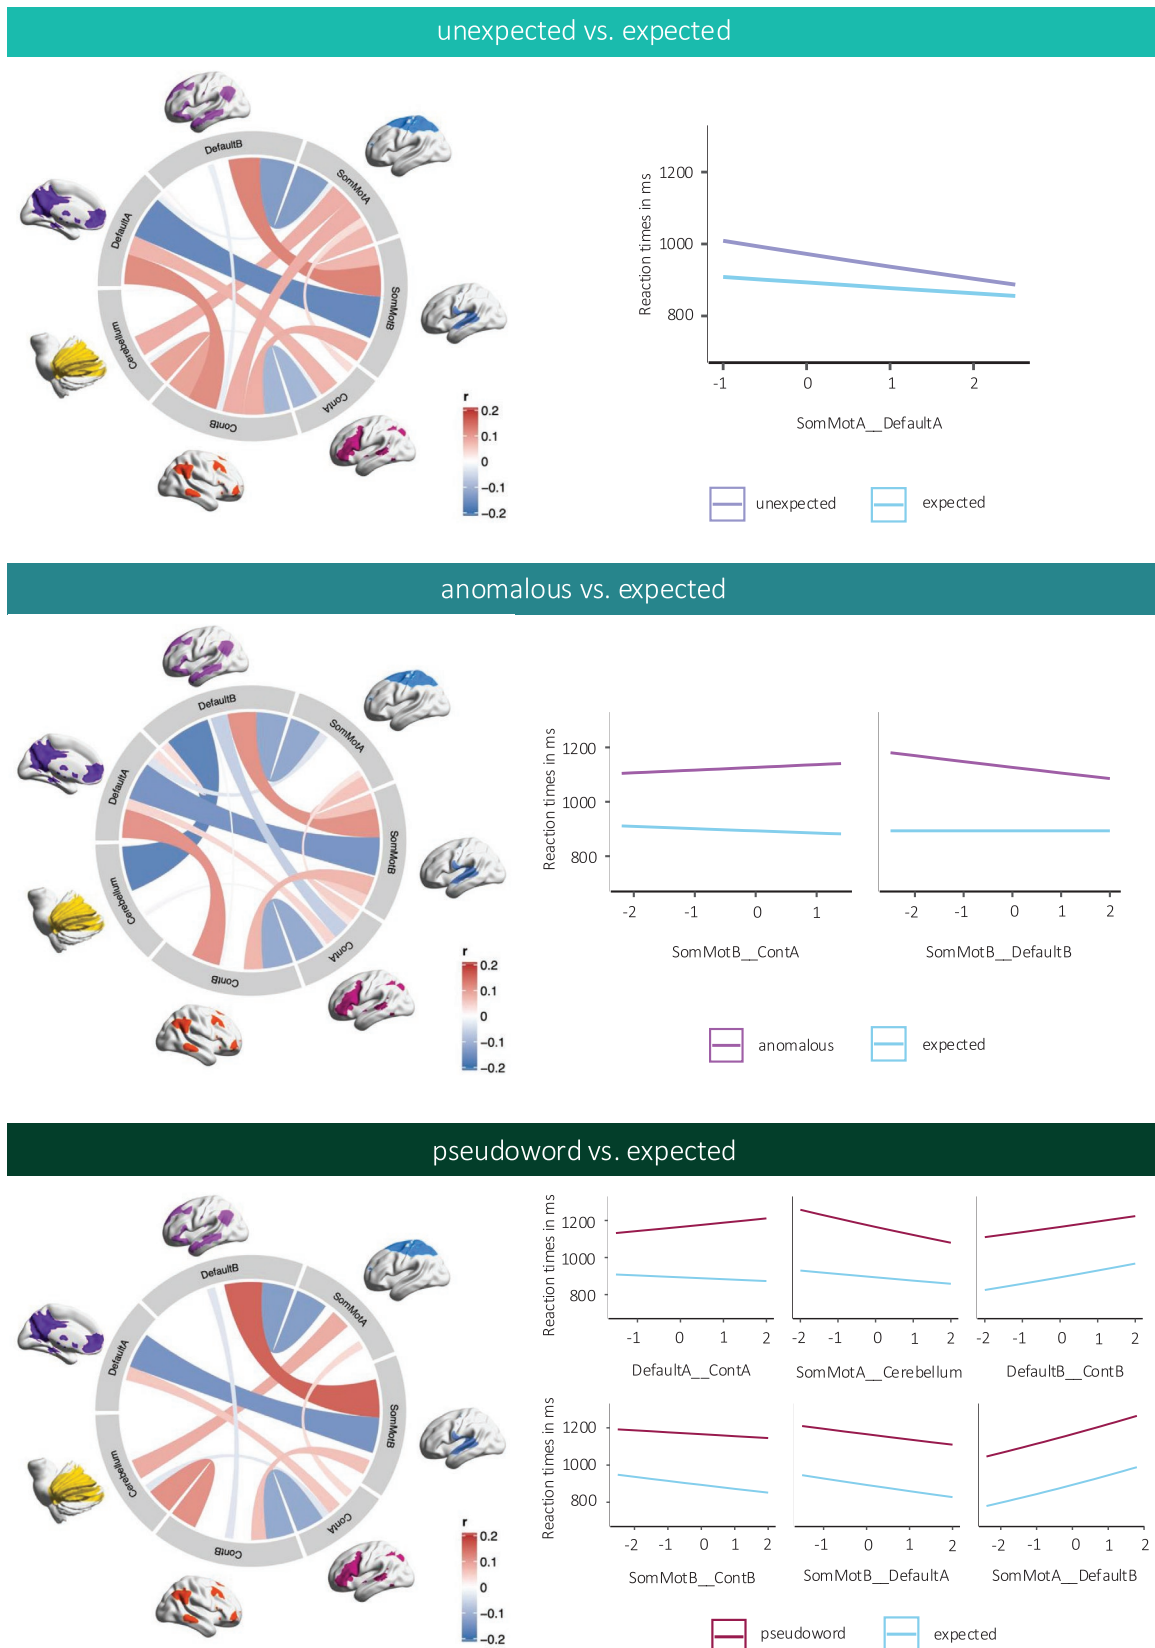

FIGURE 7 | Legend on next page.

with pseudoword endings compared to expected endings, we identified significant network interactions between DefaultA and ContA, SomMotA and Cerebellum, DefaultB and ContB, SomMotB and ContB, SomMotB and DefaultA as well as SomMotA and DefaultB. A stronger coupling between SomMotA and Cerebellum, SomMotB and ContB, and SomMotB and DefaultA resulted in faster reaction times in both conditions. The opposite pattern was found for DefaultB and ContB, as well as SomMotA and DefaultB, since a stronger coupling led to slower reaction times in both task conditions. Finally, a stronger interaction between DefaultA and ContA was associated with slower reaction times in the pseudoword condition and faster reaction times in the expected condition.

4 | Discussion

The within- and between-network dynamics underlying context-dependent, semantic integration are still poorly understood. Here, we addressed this issue by combining an auditory semantic integration paradigm with univariate task-related fMRI analyses, seed-based within-network analyses, and ICA-based between-network connectivity analyses. On the behavioral level, we reproduced the typical semantic integration effects, characterized by increased reaction times and reduced accuracy for sentences with higher integration demands (Baumgaertner, Weiller, and Büchel 2002; Hartwigsen et al. 2017). These changes were underpinned by increased task-related activity in brain areas of the semantic control network. Likewise, seed-based functional connectivity analysis revealed a significant interaction between frontal regions involved in cognitive control and subcortical or cerebellar areas. Finally, we identified seven neural networks active during semantic integration. While increasing integration demands promoted activation of task-positive networks, the default-mode networks showed more deactivation as semantic integration demands increased. As a main novel finding, between-network analyses revealed a dynamic interplay between task-positive networks associated with control and somatomotor functions and the default mode network, supporting the processing of sentences with increased semantic integration demands. Increased integration demands lead to a higher number of behaviorally relevant network interactions, suggesting that between-network coupling becomes more relevant for successful task performance as integration demands rise.

The gradual increase in response times with higher semantic integration demands in our data is in agreement with previous studies (Baumgaertner, Weiller, and Büchel 2002; Hartwigsen et al. 2017; Wawrzyniak et al. 2017) and likely reflects the suppression of the expected word as well as restructuring attempts. Likewise, a similar pattern for accuracy, but with highest error rates for anomalous trials, is supported by the same previous

studies. However, unlike the previous studies that selectively included young participants, we did not find a significant difference in reaction times for sentences with anomalous compared to pseudoword endings. This could be explained by the fact that, in our study, older age was associated with longer reaction times and higher error rates, especially for sentences with anomalous endings.

As expected, univariate results revealed a left-dominant, frontal activation pattern, including IFG, OFC, and preSMA, which increased with higher semantic integration demands (cf. Hartwigsen et al. 2017; Wawrzyniak et al. 2017). These regions are associated with cognitive control functions. While the IFG is linked to domain-specific semantic integration (e.g., Hartwigsen et al. 2017; Zhu et al. 2013) and semantic control (Jefferies 2013), the preSMA and OFC appear to be involved in domain-general control processes (Brockett and Roesch 2021; Fedorenko, Duncan, and Kanwisher 2013; Jackson 2021). The gradual increase in activation in these regions during the processing of sentences with unexpected, anomalous, and pseudoword sentence endings suggests that the higher the semantic integration demands, the more control is required to inhibit the expected word. In addition to frontal regions, temporal regions were also involved in processing sentences with increased integration demands. Specifically, we found significant activation in the posterior STG/STS. This finding was expected, as the pMTG/STS region has been implicated in the storage of lexico-semantic information (Lau, Phillips, and Poeppel 2008; Price et al. 1997) as well as lexical retrieval and selection under increased executive demands (Whitney et al. 2011, 2012). For sentences with expected endings, as well as for the contrast between word and pseudoword endings, we observed a predominantly temporo-parietal activation pattern, especially in the left IPL/AG. This is not surprising given that this region is a multimodal convergence zone, linking various semantic features of concepts and information from different modalities (Seghier 2013). In addition, previous studies confirm the critical role of this region in the processing of more predictable sentences (e.g., Humphries et al. 2007).

The gPPI analysis revealed significant task-specific interactions for the left IFG and the preSMA. Specifically, the IFG showed increased interactions with the thalamus for unexpected > expected endings. The thalamus acts as a hub region for many cognitive functions (e.g., Hwang et al. 2017) including language processing and is responsible for the transfer of lexical information to cortical regions (Fritsch, Rangus, and Nolte 2022; Nadeau and Crosson 1997). Accordingly, patients with thalamic lesions often show aphasia with mainly lexical-semantic deficits (e.g., Fritsch, Rangus, and Nolte 2022; Radanovic and Almeida 2021). Interestingly, the thalamus seems to be involved especially when automated mechanisms such as semantic priming are not

---

FIGURE 7 | Functional coupling between task-relevant networks and their behavioral relevance. Left panels: Chord diagrams show significant results of functional coupling between ICA-derived networks. Connectivity values are partial correlations. The color intensity and width of a connection indicate its correlational strength. Higher correlation values (*r*) indicate positive coupling, and negative values indicate decoupling between networks. Right panels: Correlations between network interactions and task efficiency. Plots show significant 2-way interactions between task conditions and the respective network pair for response time data. Connectivity values were mean-centered for interaction analyses. Results were FDR-corrected for multiple comparisons at $p = 0.05$. ContA/B: Control network A/B; DefaultA/B: Default mode network A/B; SomMotA/B: Somatomotor network A/B.

effective (Friederici 2006; Ketteler et al. 2008) or during difficult language tasks (Alain et al. 2005; Assaf et al. 2006). The lexical-semantic nature of our task, and the fact that we found a significant interaction between the IFG and the thalamus only for sentences with increased integration demands fits well into the bigger picture of current research. Furthermore, the preSMA showed increased interactions with the right cerebellum (Crus I-IV and Crus VI) for expected > anomalous sentence endings. An increasing number of studies suggest that the cerebellum is involved in language processing and often exhibits a crossed activation pattern with the left-dominant cortical language network. Areas Crus I-IV and Crus VI have been associated with semantic and phonological processing (Turker et al. 2023). Since both functions are crucial for the performance of our auditory lexical decision task, the involvement of the cerebellum is not surprising here. Consequently, the gPPI results emphasize the importance of subcortical and cerebellar regions in semantic integration, especially under increased demands.

Using spatial ICA, we characterized 11 higher order large-scale functional networks active during semantic integration. Cortical networks included two control networks: A left hemispheric network (ContA) as well as a right hemispheric network (ContB). Additionally, we identified the "classical" default mode network (DefaultA) and a subnetwork of the default mode network (DefaultB) which is thought to facilitate access to semantic knowledge (Smallwood et al. 2021). We also found two somatomotor networks: SomMotA likely reflects primarily motor aspects, such as button presses (Feis et al. 2015), and SomMotB, which—consistent with the auditory nature of our task—showed pronounced activation in the auditory cortex. Another network was primarily characterized by cerebellar connectivity. Furthermore, we identified a cortical network that best matched the salience/ventral attention network A (SalVentAttnA), a central visiual network (VisCent), and two networks that best aligned with the peripheral visual network (VisPeri). Overall, these results confirm our hypothesis that both task-positive and task-negative networks are involved in semantic integration. The fact that we found both default mode and control networks is consistent with the observation that networks which are typically anticorrelated during resting state become functionally integrated during semantic tasks (Krieger-Redwood et al. 2016; Martin, Saur, and Hartwigsen 2022; Martin et al. 2023).

By examining the response of the networks to increasing semantic integration demands, we identified distinct patterns of activation and deactivation across task conditions. Since we were primarily interested in networks that were relevant for successful performance of the semantic integration task, we excluded all networks that did not show significant (de/) activation for at least one task condition compared to rest from further analysis. Consequently, we explored task-related activity and between-network interactions for seven task-relevant networks (Cerebellum, ContA and ContB, DefaultA and DefaultB, as well as SomMotA and SomMotB). Our main finding was that increased semantic integration demands were associated with task-positive activation of the left hemispheric control network (ContA) and both somatomotor networks but led to deactivation of the default mode networks. We found the strongest positive activation across all conditions for SomMotB. This result was

expected as the network is mainly characterized by connectivity in the auditory cortex and thus likely reflects the auditory nature of the task. The fact that sentences with pseudoword endings elicited slightly more activity in this network than the other three conditions supports this hypothesis and could be explained by increased listening effort for pseudowords. Accordingly, Kotz (2002) showed that lexical status modulates the hemodynamic response in cerebral regions responsible for auditory word recognition. SomMotA also showed significant network activity for all four conditions, likely reflecting motor response (e.g., Feis et al. 2015) caused by the button presses. The slightly lower activity for sentences with pseudoword endings could be due to the imbalance between word and pseudoword trials. Both default mode networks showed stronger deactivation with higher semantic integration demands, although for DefaultB, this effect only reached significance for sentences with pseudoword endings. This result was expected, as the default mode network is known to play a role in self-referential information processing and monitoring the internal mental landscape (Greicius et al. 2003; Qin and Northoff 2011). These processes are particularly suppressed during cognitive tasks involving external stimuli with increased demands (e.g., Menon and D'Esposito 2022), such as sentences with unexpected, anomalous or pseudoword endings. Furthermore, evidence suggests that the default mode network activates during more "automatic" retrieval and conceptual combination tasks (Davey et al. 2016; Lanzoni et al. 2020; Price et al. 2016), such as when processing predictable sentences. The observation that DefaultB showed significant deactivation exclusively for sentences with pseudowords (which do not possess a semantic-lexical entry) is consistent with the assumption that this network contributes to semantic processing (Smallwood et al. 2021). The significant network activity of the left-dominant ContA for unexpected, anomalous, and pseudoword sentence endings, but not for expected sentence endings, likely reflects an increased level of cognitive control under increasing integration demands. ContA, together with ContB, constitutes the FPCN, a network that acts as a flexible hub for cognitive control (Dosenbach et al. 2007; Marek and Dosenbach 2018; Spreng et al. 2010). It is associated with phasic control and attention (for a review, see Menon and D'Esposito 2022) as well as error-related activity (Dosenbach et al. 2007). These skills are relevant to semantic integration under increased demands. The fact that we found activity mainly in the left-dominant ContA was expected given the semantic language task and may indicate semantic-specific control mechanisms. In contrast, the right-dominant ContB showed an opposite trend with its significant negative activation for unexpected sentence endings. Although this condition is associated with increased integration demands, it still allows for successful semantic integration (unlike the anomalous or pseudoword condition). Therefore, a possible interpretation could be that this condition relies less on right-dominant, domain-general control compared to sentences with anomalous or pseudoword endings. Additionally, the cerebellum showed significant positive network activity for sentences with anomalous endings. This finding is consistent with our gPPI results, where we found an interaction between the control region preSMA and the cerebellum for the contrast between expected and anomalous sentence endings. Thus, the cerebellum may play a supporting role in semantic processing under increased control demands.

Finally, for a direct comparison between network activity under increased integration demands and more automated semantic integration, we also examined network activity for the contrasts "unexpected vs. expected sentence endings," "anomalous vs. expected sentence endings," and "pseudoword vs. expected sentence endings." Positive network activity survived for ContA when processing sentences with anomalous and pseudoword endings compared to expected endings, highlighting the important role of the left-dominant control network in semantic integration under increased demands. DefaultA showed the only significant negative activity for sentences with pseudoword endings compared to expected endings. This result is consistent with our hypothesis that activity in the default mode network decreases with increasing integration demands.

Finally, cPPI analysis unraveled the dynamic interaction between cognitive networks under varying semantic integration demands. Overall, the results reveal distinct interaction patterns among task-positive networks and the default mode networks across varying semantic integration demands. Notably, task-positive control and somatomotor networks exhibited increased positive interactions across all task contrasts, whereas interactions with default mode networks were predominantly negative. Based on the assumption that the FPCN is crucial for domain-general cognitive control and facilitates the realization of new task states through interactions with other relevant networks (Cole et al. 2013; Marek and Dosenbach 2018; Power et al. 2011), it is not surprising that we observed strong interactions between both control networks (ContA and ContB) and somatomotor as well as default mode networks, independent of task contrast. These findings are consistent with previous research highlighting the role of task-positive networks in cognitive control and attention during increased task demands, while the default mode network is typically anticorrelated (Fox et al. 2005; Power et al. 2011). More specifically, previous studies reported an anticorrelation between the default mode network and control regions in tasks with low semantic predictability (e.g., Lanzoni et al. 2020) and there is evidence that the default mode network may be less involved in harder relative to easy semantic tasks (Humphreys et al. 2015; Humphreys, Jackson, and Lambon Ralph 2019; Humphreys and Lambon Ralph 2015). On the other hand, we also found strong positive interactions between DefaultA and the left hemispheric ContA as well as between DefaultB and SomMotB for all three task contrasts, suggesting that the default mode network might contribute to semantic integration to some extent. In fact, there is evidence that the default mode network activates during a wide variety of cognitive tasks, including episodic, linguistic, social, and emotional processes and supports the integration of external and internal information (Smallwood et al. 2021; Spreng et al. 2010). In particular, DefaultB shows a large overlap with the semantic network and might therefore contribute to performing our task, as mentioned above. A functional explanation for the default mode network interacting with other task-positive networks during semantic integration under increased demands could be that it facilitates access to semantic knowledge (Smallwood et al. 2021) and thus makes the detection of unexpected stimuli (Corbetta and Shulman 2002) more effective. Interestingly, we found a negative interaction between the two control networks (ContA and ContB) across all contrasts. This may indicate a division of labor or specialization within the control networks,

where different components are engaged depending on the specific cognitive demands of the task (Dosenbach et al. 2007). A comparison of the network couplings for the individual task contrasts revealed slight, although nonsignificant, differences in between-network interactions. First, we found the most interactions between task-positive networks for sentences with unexpected versus expected endings, likely supporting successful semantic integration under increased demands for cognitive control and attention. The "anomalous vs. expected sentence endings" contrast showed less pronounced positive network interactions but instead a notable negative interaction between the cerebellum and DefaultB. Since both the cerebellum and DefaultB are known to contribute to semantic processing (Smallwood et al. 2021; Turker et al. 2023), we interpret this negative interaction as a response to the semantic violations caused by the anomalous sentence ending. Finally, the "pseudoword vs. expected sentence endings" contrast, where semantic integration fails due to the missing lexical entry, exhibited the least statistically significant network interactions. This suggests that the absence of meaningful semantic content in pseudowords leads to reduced engagement of both task-positive and default mode networks.

We also examined the behavioral relevance of network interactions during the processing of sentences with varying semantic integration demands, revealing associations between reaction times and network coupling for each task contrast. Our main finding was that increased integration demands led to a higher number of behaviorally relevant network interactions. This suggests that the coupling becomes more relevant for successful task performance as integration demands increase. In general, stronger network interactions were associated with faster reaction times, especially for sentence endings with increased integration demands. However, for the "anomalous vs. expected endings" contrast, stronger coupling between SomMotB and ContA was associated with slower reaction times in the anomalous condition. A possible interpretation would be that subjects with increased listening effort tend to have a stronger interaction between auditory cortex and semantic control regions, which is reflected in a slower button response. In contrast, for sentences with pseudoword versus expected endings, stronger coupling between default mode and task-positive networks led to slower reaction times. Given that this is the most challenging condition, this result is expected and fits with the fact that the default mode network is often deactivated during the performance of cognitively difficult tasks (Fox et al. 2005; Power et al. 2011). In summary, our findings highlight especially the role of task-positive control and somatomotor networks in facilitating cognitive processing under increased semantic integration demands.

Our study has several limitations that should be addressed in future work. First, the relatively small sample size in combination with a wide age range makes it difficult to draw generalizable conclusions. Our sample was recruited as an age-matched control group for patients with brain tumors in an ongoing study. In the present study, we were able to show a significant age effect in the behavioral data but not in the univariate fMRI and functional connectivity analyses. Thus, our study provides first insights into semantic integration in humans along a continuous age spectrum. However, more comprehensive findings will require larger cohorts. Moreover, investigating functional connectivity during

semantic integration in a larger sample of older adults could be insightful, as there is evidence that cognitive decline is associated with increased between-network connectivity (Chan et al. 2014; Martin, Saur, and Hartwigsen 2022; Martin et al. 2023; Setton et al. 2022). Another limitation is that the fMRI methods used here are associated with poor signal in the ATL. This is critical because the ATL is thought to play an important role in semantic cognition research as a storage area for knowledge representations. Although our univariate results for the contrast between sentences with word endings and pseudoword endings showed significant activation in this area, it is possible that anterior and inferior parts are still missing. A multi-echo/multiband fMRI setup would be useful to investigate the role of this brain region in semantic integration under increased demands, especially with regard to its functional connectivity with the rest of the brain. Nevertheless, our findings pave the way for further research on semantic integration in older and clinical populations.

5 | Conclusion

The present study explored the dynamic within- and between-network interactions during semantic language processing in healthy adults across a continuous age range. We focused on the role of network interactions in semantic integration under increased demands. Behavioral and univariate data revealed typical semantic integration effects, with increased brain activity mainly in regions associated with semantic control for sentences with higher integration demands. Higher semantic control demands were also reflected by significant interactions between control-related frontal regions and subcortical or cerebellar areas. Between-network interactions further highlighted the role of task-positive control and somatomotor networks for sentence processing with increased semantic integration demands. Additionally, stronger interactions between various task-positive as well as default mode networks were associated with more efficient processing during task conditions with increased semantic integration demands. Collectively, our findings elucidate the complex network interactions underlying semantic integration, a language ability that is crucial for everyday communication. By including young, middle-aged and old adults, our findings provide first insight into semantic integration processes across the aging continuum. These results may inform future studies with healthy old as well as clinical populations.

Ethics Statement

All experimental procedures were approved by the local ethics committee of the University Hospital Halle (Saale) (reference number: 2020-073).

Consent

All participants gave written informed consent.

Conflicts of Interest

The authors declare no conflicts of interest.

Data Availability Statement

The data that support the findings of this study are available from the corresponding author upon reasonable request.
