## Danksagung

Zuallererst möchte ich mich bei Herrn Prof. Dr.-Ing. habil. W. Meusel für die Übernahme des Referates und bei Herrn Prof. Dr. K. Lorenz für das Korreferat der Masterarbeit herzlich bedanken.

Genauso möchte ich auch Herrn M. Müller, Herrn T. Dreher, Frau U. Husemann sowie Herrn C. Zahnow sowohl für die Themenstellung, als auch für die kompetente Betreuung der Arbeit und die zahlreichen Ratschläge meinen Dank aussprechen. Ebenso danke ich Herrn A. Helling für die freundliche Unterstützung am Rasterelektronenmikroskop.

Weiterhin gilt mein Dank auch allen anderen Mitarbeitern der R\&D-Abteilung „Upstream Technology" der Sartorius Stedim Biotech GmbH für die Unterstützung und die vielen hilfreichen Tipps.

Ein herzliches Dankeschön gilt auch meinen Eltern und meiner Verlobten für ihren stetigen Rückhalt während meines Studiums.

6 Conclusion and Outlook ..... 84
7 References ..... 86
8 Appendix ..... 91
9 Eidesstattliche Erklärung ..... 103

## Zusammenfassung

Da der spezifischen Wärmedurchgangskoeffizienten UA und der volumetrische Stofftransportkoeffizienten $\mathrm{k}_{\mathrm{L}}$ a eine wichtige Rolle bei der Auslegung biotechnologischer Prozesse spielen, wurden in der Vergangenheit verschiedene Methoden zur Bestimmung dieser Parameter entwickelt. Allerdings nutzen diese häufig ungenaue dynamische Verfahren zur Beschreibung von stationären Prozessen und sind hinsichtlich der Größe und Geometrie des Bioreaktors nur beschränkt einsetzbar. Deshalb war es das Ziel dieser Arbeit eine neue Methode zu entwickeln, die diese Limitationen überwindet. Der hier vorgestellte neue Ansatz basiert auf der gleichmäßigen Freisetzung von Wärme und Sauerstoff durch die Zersetzung von Wasserstoffperoxid in einer kontinuierlichen Betriebsweise. Da der Abbau von $\mathrm{H}_{2} \mathrm{O}_{2}$ unter Normalbedingungen nur unter Einwirkung eines Katalysators abläuft, wurden verschiedene Kandidaten auf ihre Eignung (u.a. bezüglich Sicherheitsaspekten und ihrer Kinetik) untersucht. Mangan-(IV)-oxid wurde als geeignet befunden. Um die Inaktivierung des $\mathrm{MnO}_{2}$ zu kompensieren wurde ein kontinuierlicher Prozess mit wiederholter Zugabe von frischem $\mathrm{MnO}_{2}$ etabliert. Weiterhin wurde ein Scale-up, ausgehend von 100 mL bis zu einem 5 Liter Glasbioreaktor (UniVessel ${ }^{\circledR}$ ), erfolgreich durchgeführt.

Um die Eignung der neuen Methode zur Charakterisierung von Bioreaktoren zu zeigen, wurde sie mit herkömmlichen Ansätzen verglichen. Sowohl mit dem neu entwickelten als auch mit einem bereits etablierten Verfahren, dass auf einer elektrisch betriebenen Wärmequelle basiert, wurden bei Leistungseinträgen von ca. 50-70 $\frac{\mathrm{W}}{\mathrm{L}}$ spezifische Wärmedurchgangskoeffizienten zwischen 17,1 und $24,8 \frac{W}{K}$ gemessen. Erste Testergebnisse bzgl. des Stofftransportes ergaben bei unterschiedlichen Verdünnungsraten bis $0,04 \mathrm{~h}^{-1}$ allerdings keine konstanten $\mathrm{k}_{\mathrm{L}} \mathrm{a}-\mathrm{Werte}$.
In nachfolgenden Studien sollten nun bezüglich des kLa höhere Zuflussraten aufgrund von gleichmäßigeren Volumenströmen überprüft werden. Darüber hinaus sind weitere Untersuchungen empfehlenswert, um den Wärmeübergang auch in größeren herkömmlichen und ebenfalls in single-use-Bioreaktoren zu analysieren.

#### Abstract

Since the specific heat transfer coefficient (UA) and the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}}$ a) play an important role for the design of biotechnological processes, different techniques were developed in the past for the determination of these parameters. However, these approaches often use imprecise dynamic methods for the description of stationary processes and are limited towards scale and geometry of the bioreactor. Therefore, the aim of this thesis was to develop a new method, which overcomes these restrictions. This new approach is based on a permanent production of heat and oxygen by the constant decomposition of hydrogen peroxide in continuous mode. Since the degradation of $\mathrm{H}_{2} \mathrm{O}_{2}$ at standard conditions only takes place by the support of a catalyst, different candidates were investigated for their potential (regarding safety issues and reaction kinetic). Manganese-(IV)-oxide was found to be suitable. To compensate the inactivation of $\mathrm{MnO}_{2}$, a continuous process with repeated feeds of fresh $\mathrm{MnO}_{2}$ was established. Subsequently, a scale-up was successfully carried out from 100 mL to a 5 litre glass bioreactor (UniVessel ${ }^{\circledR}$ )

To show the applicability of this new method for the characterisation of bioreactors, it was compared with common approaches. With the newly established technique as well as with a conventional procedure, which is based on an electrical heat source, specific heat transfer coefficients were measured in the range of $17.1-24.8 \frac{W}{K}$ for power inputs of about $50-70 \frac{W}{L}$. However, a first proof of concept regarding the mass transfer showed no constant $\mathrm{k}_{\mathrm{L}}$ a for different dilution rates up to $0.04 \mathrm{~h}^{-1}$.

Based on this, consecutive studies concerning the mass transfer should be made with higher volume flows, due to more even inflow rates. In addition, further experiments are advisable, to analyse the heat transfer in single-use bioreactors and in larger common systems.

## Chapter 1

## Introduction

Many biotechnological processes include strong exothermic reactions. The formed reaction heat sums up to 500 kJ per mole consumed oxygen (Storhas, 1994). This generated heat has to be removed from the bioreactor in order to guarantee controlled temperature conditions. While this is not problematic in small scale fermentations, cooling of bioreactors is a challenging task in greater scales, due to the decreased surface to volume ratio. For the dimensioning of bioreactors, the knowledge about the heat transfer through the walls of the reactor is very important. Overheating leads to safety issues, product loss or a decreased product quality. Therefore, procedures for a precise estimation of the heat transfer are required. By today, only one static approach with a calibration heater as a heat source is published (Regestein, 2012; Zühlke, 2015). However, it is restricted towards the bioreactor scale and its geometry. Furthermore it is not usable in single use bioreactors, which are nowadays often used in the pharmaceutical industry (Storhas, 1994; Türker, 2004).

Another key challenge for microbial fermentations and mammalian cultivations is the supply of oxygen to the cells, and therefore, to the medium. Due to the low solubility of oxygen in water and the relative high oxygen uptake rates by the cells, a steady aeration is necessary to prevent anaerobe conditions. The absorption velocity is hereby directly proportional to the phase boundary and to the concentration gradient. On that score, dispersing by stirrer or nozzles and aeration with air or pure oxygen is often applied to increase the transferred oxygen (Zlokarnik, 1999). Up to now, different measurement procedures are published. Some operate with dynamic attempts (the gassing-out method) other work with steady state measurements (the sulphite method and the exhaust gas analysis), but every method has its pros and cons and lead to different results. Therefore, new approaches, which are easy to handle, feasible for high mass transfers and result in precise outcomes, are desired (Martin, 1996; Stanbury et al., 1995).

Chapter 2

## Aim and Scope

Different approaches exist for the characterisation of the heat and mass transfer in bioreactors. In case of the heat transfer, only one method is published, which is limited by the bioreactor geometry and scale. In view of the mass transfer, often applied techniques use dynamic approaches, which fall short due to the long response time of the dissolved oxygen probes. Furthermore, these dynamic measurements differ from the static mode, which occurs in fermentations. Steady state attempts like the sulphite method deliver more accurate results, but are related with the expensive catalyst disposal. Therefore, the research question of this thesis was to develop a new method for the characterisation of bioreactors regarding heat and mass transfer, which overcomes the limitations mentioned above. This new attempt is based on a chemical heat and oxygen production by the permanent breakdown of $\mathrm{H}_{2} \mathrm{O}_{2}$, which is realised in a steady state of a continuous procedure.

The main contributions described in this thesis are multifold: First a method for the measurement of the $\mathrm{H}_{2} \mathrm{O}_{2}$ turnover by the catalysed degradation reaction is presented. This is necessary to compute the heat and the oxygen, which is set free in the reactor. Secondly, an appropriate catalyst is found and its kinetic is clarified. Thirdly, a process is developed, which allows an even heat and oxygen production by the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$. Finally, the whole procedure is scaled up from 100 mL up to a 5 litre glass bioreactor (UniVessel ${ }^{\circledR}$ ).

After the successful establishment of this process, its usability is analysed in the UniVessel ${ }^{\circledR}$ ( 5 L ) by a comparison of different conventional techniques with the newly developed procedure.

## Chapter 3

## Theoretical Background

### 3.1 Heat transfer

### 3.1.1 Types of energy transfer

The first law of thermodynamics predicates that a change of energy in an existing system is only possible if a transport of energy in or out of the system consists. Possible transports of energy are labour, heat and energy, which is conveyed by a mass flow (equation (1)) (Stephan, 2013).

| $\Delta E=W+Q+E_{M}$ |  |  |
| :--- | :--- | :--- |
| Energy difference | $\Delta E$ | $[J]$ |
| Labour, Heat | $W, Q$ | $[J]$ |
| Energy, which is tied to a mass transport | $E_{m}$ | $[J]$ |

Heat transport as a change of energy is driven by differences in temperatures. The heat flow represents the transferred heat per time unit:

$$
\begin{equation*}
\dot{Q}=\frac{d Q}{d t} \tag{2}
\end{equation*}
$$

| Heat flow $\quad \dot{Q}$ | $[W]$ |
| :--- | :--- | :--- |

Based on that, the heat flow density is defined as:

| $=\frac{d \dot{Q}}{d A}$ |  |  |
| :--- | :--- | :--- |
| Heat flux density | $\dot{q}$ | $\left[\frac{W}{m^{2}}\right]$ |
| Area, surface | $A$ | $\left[m^{2}\right]$ |

## Conduction

There are three types of heat transport. One of them is the conduction, whereby the energy transfer is caused by interactions of the molecules in a temperature-shifted material. Besides that, free electrons transport heat in metals as well. For a temperature
gradient in the direction of the coordinate x the heat flux density depends only on a material coefficient, the so called thermoconductivity:

| $\dot{q}=-\lambda \cdot \frac{d T}{d x}$ (Fourier ${ }^{\prime}$ s law) |  |  |
| :--- | :---: | :--- |
| Thermoconductivity | $\lambda$ | $\left[\frac{W}{m \cdot K}\right]$ |
| Temperature gradient | $\frac{d T}{d x}$ | $\left[\frac{K}{m}\right]$ |

For isentropic materials, which have an identic thermoconductivity in all directions in space, $\dot{q}$ is defined proportional to the temperature gradient:

$$
\begin{equation*}
\vec{q}=-\lambda \cdot \operatorname{grad} T \tag{5}
\end{equation*}
$$

According to the heat flow, which is always directed to a sink, the equation is negative. Typical values of thermoconductivity are listed up in Table $1 . \lambda$ depends on the temperature, the pressure and in materials, which are made out of different compounds, on the composition as well.

Table 1: Typical values of thermoconductivities for gases, liquids and solid materials (VDI-Gesellschaft Verfahrenstechnik und Chemieingenieurwesen, 2013).

| Physical state | $\lambda\left[\frac{\mathrm{W}}{\mathrm{m} \cdot \mathrm{K}}\right]$ |
| :---: | :---: |
| Gaseous | $0.015-0.15$ |
| Liquid | $0.1-0.65$ |
| Solid | $1-450$ |

The entirety of all temperatures in the material results in a temperature field ( $\vartheta$ ). All points of an object, which has the same temperature at the same time, are defined as isothermal areas. The heat transfer through a plane wall is illustrated by Figure 1. Since $\mathrm{r}_{1}$ and $\mathrm{r}_{2}$ are isotherms, their temperature does not differ. $\vartheta\left(\mathrm{r}_{1}\right)$ is given as $\vartheta_{\mathrm{w} 1}$ and $\vartheta\left(\mathrm{r}_{2}\right)$ as $\vartheta_{\mathrm{W} 2}$. For $\vartheta_{\mathrm{W} 1}>\vartheta_{\mathrm{W} 2}$ the heat flows from $\mathrm{r}_{1}$ to $\mathrm{r}_{2}$.

Figure 1: Schematical depiction of the heat flow through a plane wall (Baehr and Stephan, 2013).

The heat flow $(\dot{Q})$ is equal on every isotherm and unaffected by the position in the wall, because no energy can be stored in the wall under steady state conditions. Besides that, for a wall, which has a temperature independent thermoconductivity, Fourier's law is compressed from

$$
\begin{equation*}
 \tag{6}
\end{equation*}
$$

to

$$
\begin{equation*}
d \dot{Q}=-\lambda \cdot \frac{d T}{d r} \cdot A \tag{7}
\end{equation*}
$$

## Convective heat transfer through the plane wall

In flowing liquids, the energy transfer does not depend only on the conductivity but on the macroscopic movements, too. It is influenced by properties of the fluid and different process parameters (e.g. flow velocity and grade of turbulence). Special regard is given to the case of the heat transfer from a liquid to a solid phase. Ludwig Prandtl developed hereto the boundary layer theory.

At the boundary the velocity changes from zero to the maximal speed within a narrow boundary layer. Directly at the wall only conduction takes place:

| $\dot{\mathrm{q}}_{\mathrm{W}}=-\lambda\left(\frac{\mathrm{d} T}{\mathrm{dy}}\right)_{\mathrm{W}}$ |  |  |
| :--- | :--- | :--- |
| Heat flux density through a plane wall | $\dot{q}_{W}$ | $\left[\frac{W}{m^{2}}\right]$ |
| Specific length | $y$ | $[m]$ |
| Temperature gradient | $\frac{d T}{d y}$ | $\left[\frac{K}{m}\right]$ |

The heat transfer is driven by the temperature difference between the wall and the fluid.

| $\dot{\mathrm{q}}_{\mathrm{W}}=\alpha \cdot\left(T_{\mathrm{W}}-T_{\mathrm{F}}\right)$ |  |  |
| :--- | :--- | :--- |
| Heat transfer coefficient | $\alpha$ | $\left[\frac{W}{m^{2} \cdot K}\right]$ |
| Temperature in the wall | $T_{W}$ | $[K]$ |
| Temperature in the fluid | $T_{F}$ | $[K]$ |

The heat transfer coefficient condenses the complex pattern of the velocity and temperature profile. It depends on the geometry and surface roughness. Aside from that, the process parameters (e.g. velocity, grade of turbulence or direction of the stream relatively to the wall) and the properties of the fluid play an important role.

Equation (8) and (9) result in

$$
\begin{equation*}
\alpha=-\lambda \frac{\left(\frac{d T}{d y}\right)_{W}}{\left(T_{W}-T_{F}\right)} \tag{10}
\end{equation*}
$$

so that $\alpha$ depends on the temperature difference between the wall and the fluid and on the slope of the temperature profile in the wall. If the temperature progression is plotted against the wall distance, Figure 2 is formed. The heat flux density through the wall emerges from the slope of the temperature profile. The ratio of $\frac{\lambda}{\alpha}$ signifies the magnitude of the boundary layer, therefore a thick layer implies a small $\alpha$ (and thus in a minor heat transfer) and vice versa (Baehr and Stephan, 2013; Stephan, 2013).

Figure 2: Profile of the flow velocity (left) and the temperature (right) of a streaming fluid next to a wall. (Baehr and Stephan, 2013).

For the determination of $\alpha$, the temperature profile is needed. That is why for several technical relevant configurations $\alpha$-values have been calculated out of known values for $\dot{q}$ and the temperature difference $\left(T_{W}-T_{F}\right)$.

Due to the complex flow profiles next to the wall, it is often assumed that only conduction takes place in the laminar boundary layer. Therefore, the heat transfer in a bioreactor from the liquid phase in the vessel to the cooling jacket outside of it is described with a linearization approach (Türker, 2004).

$$
\begin{equation*}
\dot{Q}_{\text {Jacket }}=U \cdot A \cdot \Delta T \tag{11}
\end{equation*}
$$

| Heat flow from the reactor to the double jacket | $\dot{Q}_{\text {Jacket }}$ | $[W]$ |
| :--- | :--- | :--- |
| Overall heat transfer resistance | $U$ | $\left[\frac{\mathrm{~W}}{\mathrm{~K} \cdot \mathrm{~m}^{2}}\right]$ |

In case of a heat transfer through a plane wall the overall heat transport coefficient can be expressed as the sum of different individual resistances (Figure 3).

$$
\begin{equation*}
\frac{1}{U}=\frac{1}{\alpha_{1}}+\frac{\delta}{\lambda}+\frac{1}{\alpha_{2}} \tag{12}
\end{equation*}
$$

| Heat transfer coefficient in front of the layer | $\alpha_{1}$ | $\left[\frac{W}{m^{2} \cdot K}\right]$ |
| :--- | :---: | :--- |
| Layer thickness | $\delta$ | $[m]$ |
| Heat transfer coefficient after the layer | $\alpha_{2}$ | $\left[\frac{W}{m^{2} \cdot K}\right]$ |

Figure 3: Illustration of the occurring resistances during the heat transfer through a plane wall (Storhas, 1994).

The flow velocity, fluid properties and the vessel geometry influence the overall heat transfer resistance, which describes the conductivity of the system. Since the surface of the reactor is often difficult to measure, U and A are combined and expressed together as the specific heat transfer coefficient (UA) (Stanbury et al., 1995).

In the special case of a liquid medium at the one side of the wall, it is possible to express the relation between the entire heat transfer and the heat transfer by conduction. Therefore, $\alpha$ has to be multiplied with the overflowed length of the stationary layer and divided by the heat conductivity of the liquid. The resulting dimensionless number is called the Nusselt number (Chmiel, 2011; Stanbury et al., 1995).

$$
\begin{equation*}
N u=\frac{\alpha \cdot L}{\lambda_{l}}=\frac{\text { entire heat transfer }}{\text { heat transfer by conduction }} \tag{13}
\end{equation*}
$$

| Overflowed length of a stationary layer | $L$ | $[m]$ |
| :--- | :--- | :--- |
| Heat conductivity of the liquid | $\lambda_{l}$ | $\left[\frac{W}{m \cdot K}\right]$ |
| Nusselt number | Nu | $[-]$ |

## Radiation

Every body with a temperature higher than 0 K emits radiation, so that the following formula is valid:

| $=\dot{e}_{s}=\sigma \cdot T^{4}\left(\right.$ Boltzmann's $^{\prime}$ slaw $)$ |  |  |
| :--- | :---: | :--- |
| Energy flow density | $\dot{e}_{s}$ | $\left[\frac{W}{m^{2}}\right]$ |
| Boltzmann constant | $\sigma$ | $\left[\frac{W}{m^{2} \cdot K^{4}}\right]$ |

For real bodies, which do not emit $100 \%$ of the possible radiation, it is applied

$$
\begin{equation*}
 \tag{15}
\end{equation*}
$$

The grade of emissions depends on the material characteristics, the surface conditions, the temperature and the direction of radiation, as well (Stephan, 2013). In this thesis, radiation is predominantly neglected.

### 3.1.2 Measurement methods of UA

A static method for the determination of the heat transfer, published by Regestein, is based on a constant electrical power input (Regestein, 2012). This is performed by a calibration heater, which is dipped into the medium. By means of a high performance alternating voltage regulator a defined power input is set and the reactor is tempered by the double jacket or additional cooling fingers. Then, the specific heat transfer coefficient (UA) is calculable by the different heat flows occurring in the double jacket. Advantages of this technique are the easy handling, the low costs and the resulting reproducible outcomes. However, this approach is limited by the bioreactor scale. Further, investigations regarding heat transfer in single-use reactors are not possible with this technique. Other methods are still rare and only focus on the determination of the heat transfer coefficient $\left(\alpha_{1}\right)$ at the inner wall of the bioreactor, which is why new approaches are desired (Zühlke, 2015; Regestein, 2012; Zlokarnik, 1999).

### 3.2 Mass transfer

In microbial fermentations, the oxygen supply for cells is another important factor during the process. Due to the low solubility of oxygen in water $\left(2.18 \frac{\mathrm{mmol}}{\mathrm{L}}\left(0^{\circ} \mathrm{C}\right)\right.$, $1.03 \frac{\mathrm{mmol}}{\mathrm{L}}\left(40^{\circ} \mathrm{C}\right)$, respectively (Chmiel, 2011)) an additional aeration with air is usually needed. For a higher supply, air enriched with oxygen or pure oxygen is sometimes added. Another way of increasing the mass transfer is dispersing the gas bubbles by stirring, with the result of an increased total surface. Any more, stirring counteracts concentration gradients and thus, supports an evenly high mass transfer. In addition to that, the average gas bubble diameter is decreased. A malfunction of the aeration system may be a severe threat to the microorganisms. This problem gets special relevance for high cell density cultures. Due to the fact that an insufficient supply with oxygen may lead to a change of the metabolism, product losses or impurities are possible consequences (Chmiel, 2011; Knoll et al., 2005).

### 3.2.1 Derivation of $k_{L} a$

A common theory to describe the mass transfer between two different boundary layers is the two-film theory: Each boundary layer has a narrow, laminar film, in which no storage and only diffusion takes place. At the boundary border, the oxygen concentration is in equilibrium with the respective phase. The cores of the phases are assumed as ideal mixed and thus have constant concentrations (Figure 4) (Reiss, 2015; Chmiel, 2011).

Figure 4: Schematic illustration of oxygen transfer from a gas bubble to the medium (Storhas, 1994).

The gas-side and, respectively, liquid-side mass transfer coefficients $\mathrm{k}_{02, \mathrm{~g}}$ and $\mathrm{k}_{02,1}$ are defined by the corresponding film thickness and the diffusion coefficient:

$$
\begin{equation*}
k_{O_{2}, g} \sim \frac{D_{c, g}}{\delta_{g}} \quad k_{O_{2}, l} \sim \frac{D_{c, l}}{\delta_{l}} \tag{16}
\end{equation*}
$$

| Gas-side mass transfer coefficients | $k_{O_{2}, g}$ | $\left[\frac{m}{s}\right]$ |
| :--- | :--- | :--- |
| Diffusion coefficient of the gas boundary film | $D_{c, g}$ | $\left[\frac{m^{2}}{s}\right]$ |
| Film thickness of the gas boundary film | $\delta_{g}$ | $[\mathrm{~m}]$ |
| Liquid-side mass transfer coefficients | $k_{O_{2}, l}$ | $\left[\frac{\mathrm{~m}}{\mathrm{~s}}\right]$ |
| Diffusion coefficient of the liquid boundary film | $D_{c, l}$ | $\left[\frac{m^{2}}{s}\right]$ |
| Film thickness of the liquid boundary film | $\delta_{l}$ | $[m]$ |

The oxygen flow in the liquid film ( $\dot{n}$ ) can be expected as follows.

| $\dot{n}=k_{O_{2}, l} \cdot a \cdot\left(c_{l}{ }^{*}-c_{l}\right)$ |  |  |
| :---: | :---: | :---: |
| Amount of substance flow | $\dot{n}$ | $\left[\frac{\text { mole }}{s}\right]$ |
| Specific phase boundary interface | $a$ | $\left[\frac{1}{m}\right]$ |
| Oxygen concentrations in the gas-liquid boundary phase | $c_{l}{ }^{*}$ | $\left[\frac{\text { mole }}{L}\right]$ |
| Oxygen concentrations in the bulk liquid | $c_{l}$ | $\left[\frac{\text { mole }}{L}\right]$ |

The oxygen flow in the gas film ( $\dot{n}$ ), which correspond to the oxygen transfer rate (OTR), is given by:

| $O T R=\dot{n}=\frac{k_{O_{2, g}} \cdot a}{R \cdot T} \cdot\left(p_{O_{2, g}}-p_{O_{2}, g}{ }^{*}\right)$ |  |  |
| :--- | :--- | :--- |
| Oxygen transfer rate | OTR | $\left[\frac{\mathrm{mole}}{\mathrm{s} \cdot \mathrm{L}}\right]$ |
| Universal gas constant | $R$ | $\left[\frac{\mathrm{~J}}{\mathrm{~mole} \cdot \mathrm{~K}}\right]$ |
| Oxygen partial pressure in the gas bubble | $p_{O_{2}, g}$ | $[\mathrm{~Pa}]$ |
| Oxygen partial pressure in the gas-liquid boundary phase | $p_{O_{2, g}}{ }^{*}$ | $[\mathrm{~Pa}]$ |

These equations can be transformed to

$$
\begin{equation*}
\frac{O T R=\dot{n}=K_{l} \cdot a \cdot\left(\frac{p_{g}}{R \cdot T}-c_{l}\right)}{} \frac{K_{l}}{\text { Overall mass transfer coefficient }} \quad\left[\frac{m}{s}\right] ~ \tag{19}
\end{equation*}
$$

xygen partial pressure in the gas-hquid boundary phase $p_{O_{2}, g}$ [Pa]

These equaions can be transformed
where the overall mass transfer coefficient is described by

$$
\begin{equation*}
K_{l}=\frac{1}{\left(\frac{1}{k_{O_{2}, l}}+\frac{1}{k_{O_{2}, g}}\right)} \tag{20}
\end{equation*}
$$

The main resistance is represented by the liquid boundary layer, because $\mathrm{k}_{02, \mathrm{~g}}$ is much greater than $\mathrm{k}_{0_{2,1} \text {. }}$ This means that equation (20) can be simplified, which leads to equation (21), where $\mathrm{K}_{1}$ can be equated with $\mathrm{k}_{0_{2}, 1}$.

$$
\begin{equation*}
K_{l} \approx \frac{1}{\left(\frac{1}{k_{O_{2}, l}}\right)} \approx k_{O_{2}, l}=k_{L} \tag{21}
\end{equation*}
$$

Furthermore, it can be assumed, that $p_{g} \approx p_{g}{ }^{*}$ is valid. All in all, the mass transfer is described by

$$
\begin{equation*}
O T R=k_{L} \cdot a \cdot\left(c_{l}^{*}-c_{l}\right) \tag{22}
\end{equation*}
$$

The oxygen concentrations in the gas-liquid boundary phase ( $c_{l}{ }^{*}$ ), which is in balance with the core of the gas phase, is given by Henry's law:

$$
\begin{equation*}
c_{l}^{*}=\frac{p_{g}^{*}}{H^{p c}} \approx \frac{p_{g}}{H^{p c}} \tag{23}
\end{equation*}
$$

Henry constant (with regard to the partial pressure)
 $\left\lceil\frac{L \cdot P a}{m o l e}\right\rceil$

Since $\mathrm{k}_{\mathrm{L}}$ and a are difficult to measure, they are often combined to the volumetric oxygen transfer coefficient (kLa) (Storhas, 1994; Chmiel, 2011). Therefore, the oxygen transfer rate can be expressed as

$$
\begin{equation*}
\text { OTR }=k_{L} a \cdot\left(c_{l}{ }^{*}-c_{l}\right) \tag{24}
\end{equation*}
$$

### 3.2.2 Process technological and biological meaning of $k_{L} a$

The $\mathrm{k}_{\mathrm{L}} \mathrm{a}$, which characterises the velocity of the mass transfer, can be described as well with a correlation of the volume-specific power input and the superficial gas velocity:

$$
\begin{equation*}
k_{L} a=C \cdot\left(\frac{P}{V}\right)^{\alpha} \cdot u_{G}^{\beta} \quad(\text { Van't Riet, 1979) } \tag{25}
\end{equation*}
$$

| Volume-specific power input | $\frac{P}{V}$ | $\left[\frac{W}{L}\right]$ |
| :---: | :---: | :---: |
| Superficial gas velocity | $u_{G}$ | $\left[\frac{m}{s}\right]$ |

The mass balance for a biological system, which describes the relationship between the introduced and the consumed oxygen, is given as follows:

$$
\begin{equation*}
\frac{d c_{l}}{d t}=O T R-O U R \tag{26}
\end{equation*}
$$

Oxygen uptake rate $\quad O U R \quad\left[\frac{\text { mole }}{s \cdot L}\right]$

The OUR stands for the oxygen uptake rate of the organisms and is described by the multiplication of the specific oxygen uptake rate with the biomass concentration (Garcia-Ochoa and Gomez, 2009):

| $O U R=q_{O_{2}} \cdot c_{x}$ |  |  |
| :---: | :---: | :---: |
| Specific oxygen uptake rate | $q_{o_{2}}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~s} \cdot g}\right]$ |
| Biomass concentration | $c_{x}$ | $\left[\frac{g}{\mathrm{~L}}\right]$ |

### 3.2.3 Measurement methods of $\mathbf{k}_{\mathbf{L}} \mathbf{a}$

There are different measurement methods for the determination of the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}}$ ) , which can be split in two groups: The dynamic and the static procedures. While the dynamic approach is based on a changing oxygen level during the measurement $\left(\frac{d c_{l}}{d t} \neq 0\right)$, the static strategy works with a steady state concentration of the inflowing gas in the liquid $\left(\frac{d c_{l}}{d t}=0\right)$. This can be achieved by an oxygen sink, e.g. a microbial or chemical one.

An example for a dynamic $\mathrm{k}_{\mathrm{L}}$ a-determination is the gassing-out method where the aimed gas (e.g. oxygen) in the examined solution is previously degasified with nitrogen. Afterwards, the solution is aerated with air and the increasing oxygen concentration is registered. With the aid of the differential algorithm (equation (28) and (29), respectively), the $\mathrm{k}_{\mathrm{L}}$ is calculable. Since equation (29) has the shape of a linear equation, $\mathrm{k}_{\mathrm{L}}$ represents the slope of this function (Meusel et al., unpublished; Garcia-Ochoa and Gomez, 2009; Koepp-Bank, 2012).

$$
\begin{align*}
& \frac{d c_{l}}{d t}=k_{L} a \cdot\left(c^{*}{ }_{l}-c_{l}(t)\right)  \tag{28}\\
& \ln \left(\frac{c^{*}{ }_{l}-c_{0}}{c^{*}{ }_{l}-c_{l}(t)}\right)=k_{L} a \cdot t \tag{29}
\end{align*}
$$

| Time dependent oxygen concentration in the medium | $c_{l}(t)$ | $\left[\frac{\mathrm{mole}}{\mathrm{L}}\right]$ |
| :---: | :--- | :---: |
| Oxygen concentration in the medium at $\mathrm{t}=0$ | $c_{0}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |

The main advantages of this approach are the quick evaluation and the low costs. The determination is possible under non-sterile settings and the utilised chemicals are harmless considering safety issues. Further, a wide span of different process conditions can be studied without limitations due to biological influences and a comparison of different systems is easily applied. However, due to constantly changing oxygen concentration in the medium, this strategy is vulnerable, due to the response time of the dissolved oxygen probe. Furthermore, the difference between the current and the saturation concentration decreases over time. Hence, the driving force for the mass transfer decreases gradually. Therefore, the $\mathrm{k}_{\mathrm{L}}$ a determined with dynamic methods will be smaller compared to steady state approaches (Meusel et al., unpublished; GarciaOchoa and Gomez, 2009).

For this reason, the stationary sulphite method has to be mentioned (Chmiel, 2011). Under the influence of a catalyst like copper or cobalt, sulphite is oxidized by the dissolved oxygen to sulphate (equation (30)). The amount of non-converted sodium sulphite is determined iodometrically.

$$
\begin{equation*}
2 \mathrm{Na}_{2} \mathrm{SO}_{3}+\mathrm{O}_{2} \xrightarrow{\text { Catalyst }} 2 \mathrm{Na}_{2} \mathrm{SO}_{4} \tag{30}
\end{equation*}
$$

The oxygen concentration is always zero, because the entire supplied oxygen is consumed in the reaction described above. The $\mathrm{O}_{2}$-mass-flow is determined by the timedependent change of the normality of the sulphite-solution. By the fast reaction rate, it can be assumed that the consumption of $\mathrm{O}_{2}$ takes place next to the boundary layer and
consequently, increases the difference between the gas bubble and the boundary layer as well as the mass-transfer-driving-force. Thus, the obtained $\mathrm{k}_{\mathrm{L}}$ a will be overestimated compared to biological systems (Martin, 1996; Zlokarnik, 1999; Chmiel, 2011; GarciaOchoa and Gomez, 2009; Storhas, 1994).

Another disadvantage of this method is the disposal of cobalt. Furthermore, in single-use bioreactors only one measurement per bag is possible, due to residues of the catalyst, whereas the gassing-out method allows multiple measurements with one bag.

Another static method to determine the $\mathrm{k}_{\mathrm{L}}$ a is based on the exhaust gas analysis during a microbial fermentation (Nagraik, 2015). The oxygen uptake rate is calculable by equation (31).

| OUR $=\frac{\dot{V}_{\text {spec.gas }} \cdot p}{V \cdot R \cdot T} \cdot\left(x_{O_{2, \text { in }}}-\frac{1-x_{O_{2}, \text { in }}-x_{C}}{1-x_{O_{2}, \text { out }}-x_{C},}\right.$ | $\frac{\text {,in }}{} \cdot x_{O_{2}, \text { out }}$ |  |
| :---: | :---: | :---: |
| Specific gas flow rate | $\dot{V}_{\text {spec.gas }}$ | $\left\lceil\frac{L}{L \cdot s}\right\rceil$ |
| Pressure | $p$ | [Pa] |
| Volume | V | [L] |
| Oxygen mole fraction (inlet gas flow) | $x_{O_{2}, \text { in }}$ | [-] |
| Oxygen mole fraction (outlet gas flow) | $x_{O_{2}, \text { out }}$ | [-] |
| Carbon dioxide mole fraction (inlet gas flow) | $x_{C O}{ }_{\text {, in }}$ | [-] |
| Carbon dioxide mole fraction (outlet gas flow) | $x_{C O_{2}, \text { out }}$ | [-] |

$$
\begin{equation*}
k_{L} a=\frac{O U R}{c^{*}{ }_{l}-c_{l}} \tag{32}
\end{equation*}
$$

The main advantage of this steady state technique is the independency of modelsystems and the related realistic conditions. However, the process parameters are comparatively fixed. They cannot be changed during the fermentation to study different experimental settings.

### 3.3 Decomposition of hydrogen peroxide as a potential source of heat and oxygen for thermodynamic experiments

For the characterisation of bioreactors, the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ is a potential source of heat by its high reaction enthalpy ( $-98.2 \frac{\mathrm{~kJ}}{\mathrm{~mole}}$ ) and oxygen. Hydrogen peroxide is a highly reactive liquid with a density of $1.1 \frac{\mathrm{~kg}}{\mathrm{~L}}$ (at $20^{\circ} \mathrm{C}$ and a concentration of $30 \mathrm{wt} . \%$ ) and a molarity of $34.0 \frac{\mathrm{~g}}{\text { mole }}$. Furthermore, it is a cheap compound ${ }^{1}$ and the formed products are considered as harmless. However, hydrogen peroxide as the educt is corrosive and oxidizing. The chemical reaction is described as

$$
\begin{equation*}
2 \mathrm{H}_{2} \mathrm{O}_{2} \rightarrow 2 \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2} \tag{33}
\end{equation*}
$$

and should be supported by a catalyst to ensure a steady and safe process. Possible catalysts are the enzyme catalase, $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ and $\mathrm{MnO}_{2}$ among others (Müller, 2015).

Compared to a calibration heater for the heat production in bioreactors (Regestein, 2012), the hydrogen peroxide-method has the advantage to work independently of the bioreactor scale and geometry. Thus, it can be used in very small, very big and wavemixed bioreactors and allows an evenly heat production throughout the whole system. In addition, the breakdown of $\mathrm{H}_{2} \mathrm{O}_{2}$ delivers high amounts of oxygen, which can be used for the measurement of the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}} \mathrm{a}$ ) (Müller, 2015). As distinct to common methods, this procedure leads to a supersaturation of the dissolved oxygen concentration by the formation of dissolved gas in the liquid phase. Values of

[^0]130-300 \% have been published in the literature (Martin, 1996). However, it has to be considered that the accomplished $\mathrm{k}_{\mathrm{L}}$ a measured with this method was higher compared to the results of other procedures, because of bubble nucleation. This effect was observed especially in non-coalescing media with low $\mathrm{k}_{\mathrm{L}} \mathrm{a}$-values because newly formed bubbles strongly increased the interfacial surface and caused turbulences (Linek et al., 1996; Martin, 1996; Hickman, 1988).

### 3.3.1 Different catalysts for the digestion of $\mathrm{H}_{2} \mathrm{O}_{2}$ and their reaction mechanisms

### 3.3.1.1 Catalase

Catalase (E.C. 1.11.1.6) naturally occurs in the liver, the kidney, conjunctive tissue and red blood cells. It is present in plants as well, in particular in some storage organelles like potato nodules. It regulates the hydrogen peroxide-level and protects SH-proteins like haemoglobin from the oxidizing effect of $\mathrm{H}_{2} \mathrm{O}_{2}$ (Reißmann, 2015).

Catalase has a quaternary structure with four subunits (similar to haemoglobin). Each subunit has a haem group, more than 500 amino acids and weighs about 60 kDa . In contrast to haemoglobin, the iron atom at the centre of the porphyrin ring has a charge of + III instead of + II. The metal ion can be transformed to +V during the catalysis. In comparison to free iron ions, the enzyme reaction is distinctly faster. Nevertheless, the homogenous catalysis with $\mathrm{Fe}^{3+}$ has been investigated as well (Eduard-Job-Stiftung für Thermo- und Stoffdynamik, 2015).

### 3.3.1.2 Iron nitrate

Two mechanisms have been found for the iron driven decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ (Eduard-Job-Stiftung für Thermo- und Stoffdynamik, 2015): The Kremer-Stein-mechanism describes the reaction with a changing oxidation number of iron from ( +III ) to $(+\mathrm{V})$ and back:

$$
\begin{gather*}
\mathrm{Fe}^{3+}+\mathrm{H}_{2} \mathrm{O}_{2} \leftrightarrow\left[\mathrm{Fe}^{+\mathrm{III} \mathrm{OOH}]^{2+}+\mathrm{H}^{+}}\right.  \tag{34}\\
\leftrightarrow\left[\mathrm{Fe}^{+V} \mathrm{O}\right]^{3+}+\mathrm{H}_{2} \mathrm{O} \xrightarrow{+\mathrm{H}_{2} \mathrm{O}_{2}} \mathrm{Fe}^{3+}+2 \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2}
\end{gather*}
$$

The Haber-Weiss-mechanism depicts the process with a radical chain reaction, where iron (+III) is oxidized to iron ( + II) and back. Apart from the high reaction enthalpy, this explains the fast reaction kinetics.

$$
\begin{equation*}
\text { Initiation: } \quad \mathrm{Fe}^{3+}+\mathrm{H}_{2} \mathrm{O}_{2} \leftrightarrow\left[\mathrm{Fe}^{+I I I} \mathrm{OOH}\right]^{2+}+\mathrm{H}^{+} \leftrightarrow \mathrm{Fe}^{2+}+\mathrm{HOO} \cdot+\mathrm{H}^{+} \tag{35}
\end{equation*}
$$

Continuation:

$$
\begin{gathered}
\mathrm{Fe}^{2+}+\mathrm{H}_{2} \mathrm{O}_{2} \rightarrow \mathrm{Fe}^{3+}+2 \mathrm{OH} \cdot \\
\mathrm{Fe}^{3+}+\mathrm{H}_{2} \mathrm{O}_{2}+\mathrm{OH} \cdot \rightarrow \mathrm{Fe}^{3+}+\mathrm{HOO} \cdot+\mathrm{H}_{2} \mathrm{O} \\
\rightarrow \mathrm{Fe}^{2+}+\mathrm{H}^{+}+\mathrm{O}_{2}+\mathrm{H}_{2} \mathrm{O}
\end{gathered}
$$

### 3.3.1.3 Manganese-(IV)-oxide

Furthermore, manganese dioxide (also known as pyrolysite) has been used as a heterogeneous catalyst in the process described above. Thus, the size of the surface can be a limiting factor for the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ (Martin, 1996; Eduard-Job-Stiftung für Thermo- und Stoffdynamik, 2015; Hickman, 1988; Reißmann, 2015).

The reaction mechanism is proposed as followed (Broughton and Wentworth, 1947):

$$
\begin{gather*}
\mathrm{MnO}_{2}+\mathrm{H}_{2} \mathrm{O}_{2}+2 \mathrm{H}^{+} \rightarrow \mathrm{Mn}^{++}+2 \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2}  \tag{36}\\
\mathrm{Mn}^{++}+2 \mathrm{H}_{2} \mathrm{O}_{2} \leftrightarrow \mathrm{Mn}(\mathrm{OH})_{2}+2 \mathrm{H}^{+} \\
\mathrm{Mn}(\mathrm{OH})_{2}+\mathrm{H}_{2} \mathrm{O}_{2} \rightarrow \mathrm{MnO}_{2}+2 \mathrm{H}_{2} \mathrm{O}
\end{gather*}
$$

Overall reaction: $\quad 2 \mathrm{H}_{2} \mathrm{O}_{2} \rightarrow 2 \mathrm{H}_{2} \mathrm{O}+\mathrm{O}_{2}$

Different publications showed, that the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ is benefitted in alkaline medium compared to neutral or acidic medium (maximum of catalytic activity: pH 11.5 12.0 (Kanungo et al., 1981; Omar, 2014)). The literature mentions for the $\mathrm{MnO}_{2}$ supported digestion activation energies of $58 \frac{\mathrm{~kJ}}{\mathrm{~mole}}$ and, respectively, $82 \frac{\mathrm{~kJ}}{\mathrm{~mole}}$ (Elprince and Mohamed, 1992; Dolhun, 2015).

### 3.3.2 Reaction kinetics of the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$

The breakdown of hydrogen peroxide follows a first order reaction. Hence, the change of the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration per time is given by

$$
\begin{equation*}
\frac{d c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)}{d t}=-k \cdot c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right) \tag{37}
\end{equation*}
$$

$$
\mathrm{H}_{2} \mathrm{O}_{2} \text { concentration } \quad c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right) \quad\left[\frac{\text { mole }}{L}\right]
$$

$$
\text { Reaction rate } \quad k \quad\left[\frac{1}{h}\right]
$$

Because the reaction rate depends on the amount of catalyst, it is defined as

$$
\begin{equation*}
 \tag{38}
\end{equation*}
$$

Therefore, $\mathrm{k}^{\prime}$ is one of the most important parameters for the dimensioning of experiments (Do et al., 2009; Elprince et al., 2008; Akhtar et al., 2012).

As mentioned before, the pH has an influence on the reaction kinetics (3.3.1). For a defined range, the literature brings up the following coherence for $\mathrm{MnO}_{2}$ (Elprince et al., 2008):

$$
\begin{equation*}
k=k^{\prime} \cdot c(C A T) \cdot 10^{\frac{-p H}{4}} \tag{39}
\end{equation*}
$$

Since this range refers to soil samples and not to pure $\mathrm{MnO}_{2}$, it is not completely transferable. Nevertheless, the pH has still to be taken into account. However, if the $\mathrm{MnO}_{2}$ is suspended in PBS buffer, the pH will not change during the experiment and the additional factor can be integrated in the pseudo reaction rate $\mathrm{k}^{\prime}$.

In a continuous mode the steady state balance equations for the hydrogen peroxide concentration in an ideally mixed vessel is given by

$$
\begin{equation*}
0=D \cdot c\left(H_{2} O_{2}\right)_{i}-D \cdot c\left(H_{2} O_{2}\right)_{o}-k^{\prime} \cdot c(C A T) \cdot c\left(H_{2} O_{2}\right)_{o} \tag{40}
\end{equation*}
$$

| Dilution rate | $D$ | $\left[\frac{1}{h}\right]$ |
| :---: | :--- | :--- |
| Inflowing $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration | $c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |
| Outflowing $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration | $c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{o}$ | $\left[\frac{\text { mole }}{\mathrm{L}}\right]$ |

The equation can be transformed to

$$
\begin{equation*}
0=D \cdot c\left(H_{2} O_{2}\right)_{i}-\left(D+k^{\prime} \cdot c(C A T)\right) \cdot c\left(H_{2} O_{2}\right)_{o} \tag{41}
\end{equation*}
$$

Since the turnover is described by

| $\qquad=\left(1-\frac{c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{o}}{c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i}}\right) \cdot 100$ |  |
| :---: | :---: |
| Turnover $\quad X$ | [\%] |

converting and insertion of equation (41) in equation (42) leads to

$$
\begin{equation*}
X=\frac{k^{\prime} \cdot c(C A T) \cdot \frac{1}{D}}{1+k^{\prime} \cdot c(C A T) \cdot \frac{1}{D}} \tag{43}
\end{equation*}
$$

If a constant turnover is adjusted, which is feasible in continuous mode, it is possible to calculate precisely the reaction rate.

### 3.3.3 Determination of the $\mathrm{H}_{2} \mathrm{O}_{2}$ turnover

For the calculation of the exact $\mathrm{H}_{2} \mathrm{O}_{2}$ turnover, a measurement of the current concentration is helpful. The literature recommends a two-step colorimetric method (Vogel and Mendham, 2000; Dokuzovic, 2015). First of all, the colourless hydrogen peroxide solution is mixed with an acidified potassium iodide solution. Attributable to the formation of elementary iodine the liquid changes its colour instantly to dark red and, respectively, brown. In this step, the complete $\mathrm{H}_{2} \mathrm{O}_{2}$ is depleted due to an overflow of the other components in the solution.

$$
\begin{array}{cc}
\mathrm{H}_{2} \mathrm{O}_{2}+2 \mathrm{HCl}+2 \mathrm{KI} & \rightarrow 2 \mathrm{H}_{2} \mathrm{O}+\mathrm{I}_{2}+2 \mathrm{KCl}  \tag{44}\\
\text { (colourless) } & \text { (dark red / brown) }
\end{array}
$$

Afterwards, a sodium thiosulfate solution is titrated until the colour almost reaches the colourless shape again.

$$
\begin{align*}
& 2 \mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}+\mathrm{I}_{2} \rightarrow 2 \mathrm{NaI}+\mathrm{Na}_{2} \mathrm{~S}_{4} \mathrm{O}_{6}  \tag{45}\\
& \text { (dark red / brown) } \quad \text { (colourless) }
\end{align*}
$$

Subsequently, a starch solution is added to improve the sensitivity of the colorimetric determination. By the incorporation of polyiodide into the helix shaped starch molecules the liquid turns dark purple and black, respectively. Next, more sodium thiosulfate is titrated until the dark dye is completely ceased. Since the $\mathrm{H}_{2} \mathrm{O}_{2}$ reacts stoichiometrically with the iodide, the initial amount of $\mathrm{H}_{2} \mathrm{O}_{2}$ is calculable.

Compared with the often used permanganate method (which is based on equation (46)) the procedure described above has the advantage to be less effected by stabilisers, which are sometimes added to the hydrogen peroxide solution. Furthermore, too high concentrations of $\mathrm{H}_{2} \mathrm{O}_{2}$ result in the formation of $\mathrm{MnO}_{2}$, which would decompose the compound of interest (Vogel and Mendham, 2000).

$$
\begin{equation*}
2 \mathrm{MnO}_{4}^{-}+5 \mathrm{H}_{2} \mathrm{O}_{2}+6 \mathrm{H}^{+} \rightarrow 2 \mathrm{Mn}^{2+}+5 \mathrm{O}_{2}+8 \mathrm{H}_{2} \mathrm{O} \tag{46}
\end{equation*}
$$

## Material and Methods

### 4.1 Material

Chemicals, enzymes and devices are listed up in Table 10 and, respectively, Table 11 in the appendix.

### 4.2 Preparation of the solutions

$1 \mathrm{wt} . \%$ starch solution ( 100 mL )
For the preparation of the starch solution, $1 \pm 0.05 \mathrm{~g}$ starch was weighed out in a beaker and $10 \pm 0.5 \mathrm{~mL}$ RO-water was added to the starch. The mixture was stirred thoroughly with a scoop before it was added to $80 \pm 0.5 \mathrm{~mL}$ of boiling RO-water. The starch residues were transferred from the beaker with $10 \pm 0.5 \mathrm{~mL}$ RO-water and the starch solution was agitated with a magnetic stir bar until it got clear. Finally, the starch solution was cooled down to room temperature and stored at $5^{\circ} \mathrm{C}$.

### 0.1 M sodium thiosulfate solution ( 100 mL )

The sodium thiosulfate solution was prepared by weighing of $1.58 \pm 0.05 \mathrm{~g} \mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}$. After the salt was transferred to a graduated flask ( 100 mL ), a magnetic stir bar and $80 \pm$ 0.5 mL RO-water were added. The solution was stirred until the sodium thiosulfate was completely dissolved. Then, the graduated flask was filled up to 100 mL .

### 0.24 M potassium iodide solution ( 500 mL )

For the production of the potassium iodide solution, $20 \pm 0.05 \mathrm{~g}$ potassium iodide was weighed out and the salt was added to a graduated flask ( 500 mL ). Next, a magnetic stir bar and $400 \pm 0.5 \mathrm{~mL}$ RO-water were added. The liquid was stirred until the potassium iodide was completely dissolved. Subsequently, the flask was filled up to 500 mL . As much 50 mL tubes as samples were expected were filled with 32 mL KI -solution.

## 10x PBS-buffer ( 1000 mL )

The 10 -fold PBS-buffer was prepared by weighing out $80 \pm 0.1 \mathrm{~g} \mathrm{NaCl}, 2.0 \pm 0.05 \mathrm{~g} \mathrm{KCl}$, $14.2 \pm 0.1 \mathrm{~g} \mathrm{Na}_{2} \mathrm{HPO}_{4}$ and $2.4 \mathrm{~g} \pm 0.05 \mathrm{KH}_{2} \mathrm{PO}_{4}$. The salts were transferred to a graduated flask ( 1 L ) and dissolved completely by means of a magnetic stir bar and 800 mL RO-water. After that, the graduated flask was filled up to the calibration mark. Before the PBS-buffer was used, a 10 -fold dilution was carried out.

### 4.3 Determination of the $\mathrm{H}_{2} \mathrm{O}_{2}$ turnover

The prefilled KI-solution was added to 4 mL of hydrochloric acid (32 wt. \%) in another 50 mL tube and subsequently, the sample was added. The recommended sample volume was estimated by Table 2. The sealed 50 mL tube was shaken and the solution was filled to a 50 mL beaker. Afterwards, the solution was stirred with a magnetic stir bar. After the fluid was completely mixed, the sodium thiosulfate solution was titrated until the solution turned almost colourless. Next, 0.8 mL of the starch solution was added. After 15 seconds, the $\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}$ solution was titrated again until the mixture bleached. The colour changes during the procedure are shown in Figure 5.

Table 2: Recommended sample volume for different estimated $\mathrm{H}_{2} \mathrm{O}_{2}$ concentrations.

| Concentration $\left(\frac{\text { mole }}{L}\right)$ | Turnover $[\%]^{*}$ | Sample volume $[\mathrm{mL}]$ |
| :---: | :---: | :---: |
| 9.79 | 0.0 | 0.02 |
| 4.90 | 50.0 | 0.04 |
| 2.45 | 75.0 | 0.08 |
| 1.22 | 87.5 | 0.16 |
| 0.61 | 93.8 | 0.32 |
| 0.31 | 96.9 | 0.64 |
| 0.15 | 98.4 | 1.28 |
| 0.05 | 99.5 | 4.00 |

*Turnover of $\mathrm{H}_{2} \mathrm{O}_{2}$ in regard to an initial concentration of $9.80 \frac{\text { mole }}{L}$ and $30 \mathrm{wt} . \%$, respectively.

Figure 5: Colour changes during the measurement of the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration. From left to right: 1. Acidified KI-solution before the addition of the $\mathrm{H}_{2} \mathrm{O}_{2}$ sample / 2. Acidified KI-solution after the addition of the $\mathrm{H}_{2} \mathrm{O}_{2}$ sample / 3a. and 3b. Titration of $\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3} / 4$. Addition of the starch solution / 5. End point of the titration.

Since every $\mathrm{H}_{2} \mathrm{O}_{2}$ molecule forms one iodine molecule, which reduces two thiosulfate molecules, the initial concentration of $\mathrm{H}_{2} \mathrm{O}_{2}$ is calculated by the following equation:

| $c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)=\frac{V_{\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}} \cdot c\left(\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}\right) \cdot \frac{1}{2}}{V_{\text {Sample }}}$ |  |  |
| :--- | :--- | :--- |
| Sodium thiosulfate volume | $V_{\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}}$ | $[\mathrm{~L}]$ |
| Sodium thiosulfate concentration | $c\left(\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}\right)$ | $\left[\frac{\mathrm{mole}}{\mathrm{L}}\right]$ |
| Sample volume | $V_{\text {Sample }}$ | $[L]$ |

Subsequently, the turnover is computable by equation (42).

### 4.4 Establishment of an appropriate catalyst for the decomposition of $\mathbf{H}_{2} \mathbf{O}_{2}$

Several catalysts were examined for their ability and suitability to decompose $\mathrm{H}_{2} \mathrm{O}_{2}$. Therefore, batch-experiments in a scale of 0.1 L with different catalyst-concentrations were performed in order to approximately determine the pseudo reaction rate. The experiments were carried out with an initial hydrogen peroxide concentration of $1.5 \frac{\text { mole }}{L}$. This concentration was chosen, because this amount of $\mathrm{H}_{2} \mathrm{O}_{2}$ can lead to a maximal temperature increase of about $35^{\circ} \mathrm{C}$ in the medium and is therefore harmless in view of safety issues. A 250 mL beaker, placed on a stir plate, served as a reaction
vessel. It was insulated to reduce the cooling effect by the environment. The magnetic stirrer was adjusted in a way so that ideal mixing was guaranteed (Figure 6).

Figure 6: Experimental setup for investigations of different catalysts concerning their ability to decompose $\mathrm{H}_{2} \mathrm{O}_{2}$.

The $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration was measured with the previously mentioned procedure (4.3). Since the kinetic of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition is given by equation (37) and (38), $\mathrm{k}^{\prime}$ is calculable by:

$$
\begin{equation*}
k^{\prime}=\frac{k}{c(C A T)} \tag{48}
\end{equation*}
$$

The time depended temperature profile was registered continuously (measurements every 5 seconds).

The experiments with catalase were executed in potassium phosphate buffer ( pH 7 ), whereas RO -water was utilised for $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$. PBS-Buffer ( pH 7 ) was used for $\mathrm{MnO}_{2}$, because manganese oxide does not inhibit coalescence, due to its insolubility in water. In the case of $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$, the catalyst dissociates by itself in $\mathrm{Fe}^{3+}$ and $\mathrm{NO}^{3-}$ and therefore, lead to a non-coalescent medium.

### 4.5 Establishment of a continuous heat production method based on the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$

For the calculation of the specific heat transfer coefficient (UA) and the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}}$ a) a continuous process was established with the aim of a constant heat and oxygen release by the steady degradation of hydrogen peroxide. Furthermore, with such a process it is possible to determine different kinetic parameters very precisely. The experimental setup was installed as follows: Hydrogen peroxide was pumped into a 250 mL beaker and later on in a 2 and 5 litre reactor, respectively (UniVessel®, multi-use) by a Watson Marlow peristaltic pump. Depending on the needed flow rate, tubes with different diameters were used. The exact determination of the flow rate was carried out by weighing the $\mathrm{H}_{2} \mathrm{O}_{2}$ supply bottle and, respectively, the waste bottle. The transfer of the medium was performed by a tube, which was dipped into the medium. The 2 and 5 litre bioreactor were equipped with baffles and a double jacket, which was used for temperature regulation. The cooling water was supplied by the Frigomix 1000. The 2 L reactor was only used for small scale experiments with very low amounts of medium ( 0.35 L and 1 L ) during the establishment of the new method and the scale-up. Therefore, a 3-blade segment impeller (diameter of 54 mm ) offered an ideally mixed system. In the 5 L reactor ( 3.5 L medium) the 6 -blade disk-impeller (diameter of 75 mm ) was chosen, due to its comparatively better mixing properties in larger scales (Figure 7- Figure 10).

Figure 7: 3-blade segment impeller (left), 6-blade disk impeller (center) and schematic illustration of the UniVessel ${ }^{\circledR}$ (2 L and 5 L ) (right).

Figure 8: Experimental setup for the establishment of a constant heat and oxygen production method in a 250 mL beaker based on the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$.

Samples for the determination of $\mathrm{H}_{2} \mathrm{O}_{2}$ were taken out of the 250 mL beaker directly by a pipette and, in case of the UniVessel ${ }^{\circledR}$ ( 2 L and 5 L , respectively), by two syringes: One for rinsing the tubing ( 3 mL ) and the other one for the taking out of the sample ( 1.5 mL ). The samples were transferred to a micro reaction vessel (Eppendorf), wherefrom a defined volume was taken, added to a KI-solution, which was freshly acidified with HCl , and analysed as described above (4.3).

Subsequently, the medium, taken from the reactor to wash the tubing (and, in case of the UniVessel ${ }^{\circledR}(2 \mathrm{~L})$, the leftover in the micro reaction vessel), were pushed back into the system by a third syringe. In case of the Univessel ${ }^{\circledR}$ (5 L), the pass back of the leftover was renounced, due to the insignificance of the small catalyst traces compared to the reactor volume and for reasons of simplifications. Afterwards, 5 mL of ambient air was pushed through the syringes to remove residues from the sampling system and to make both the catalyst and the substrate available to the reaction again.

The sampling system as well as the outflow was placed next to the stirrer in a zone of high mixing and fastened with cable tie at the temperature probe.

Figure 9: Experimental setup for the establishment of a constant heat and oxygen production method in the UniVessel ${ }^{\circledR}$ (2 L) based on the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$.

Figure 10: Experimental setup for the establishment of a constant heat and oxygen production method in the UniVessel ${ }^{\circledR}$ ( 5 L ) based on the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$.

Prior to all experiments, the concentration of the $\mathrm{H}_{2} \mathrm{O}_{2}$ stock solution was tested, to guarantee a constant quality and reproducible results. The stock solution was stored at $5^{\circ} \mathrm{C}$ and warmed up to room temperature before it was used, to ensure a constant density and therefore, a constant flow.

### 4.6 Determination of UA in the UniVessel ${ }^{\circledR}$ ( 5 L )

For the measurement of UA the experiments were performed in the UniVessel ${ }^{\circledR}$ (5 L) and executed like described above (4.5). To overcome the dilution- and inactivation effect, which were discovered in later experiments (5.3), the following feeding strategy was used: In the beginning a $\mathrm{MnO}_{2}$ concentration of $6 \frac{g}{L}$ was introduced and after every hour, a feed of $3 \frac{g}{L}$, suspended in 40 mL RO-water, was added. Temperature probes were installed at the in- and outlet of the cooling jacket and a mass flow measurement device was assembled in the cooling circulation (Figure 11).

For comparative studies, not only a heat supply by the degradation of hydrogen peroxide was studied, but also an electrically heat supply by calibration heaters was utilised (Figure 12). These calibration heaters had a maximum power input of 250 W and, respectively, 500 W and were set with a high performance alternating voltage regulator to the required set points.

Figure 11: Experimental setup for the investigation of the heat transfer through the wall of the UniVessel ${ }^{\circledR}$ ( 5 L ). Heat is supplied chemically by the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$. Compared to Figure 10 the temperature probes at the in- and outlet of the double jacket and, furthermore, the mass flow meter is shown.

Figure 12: Experimental setup for the investigation of the heat transfer through the wall of the UniVessel ${ }^{\circledR}$ ( 5 L ). Heat is supplied electrically by a calibration heater.

### 4.7 Determination of $\mathrm{k}_{\mathrm{L}} \mathrm{a}$ in the UniVessel ${ }^{\circledR}$ ( 5 L )

The experimental setup for the measurement of the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}}$ ) was similar to the heat transfer investigations (Figure 13). At first, the bioreactor was filled with 1x PBS-buffer ( 3.5 L ), agitated ( 500 rpm ), tempered ( $30^{\circ} \mathrm{C}$ ) and aerated with nitrogen $\left(1 \frac{L}{\min }\right)$. After the $\mathrm{pO}_{2}$ and the temperature probe showed constant values, the $\mathrm{pO}_{2}$ probe was recalibrated, if necessary. Subsequently, $6 \frac{g}{L} \mathrm{MnO}_{2}$ was added and the aeration was stopped. Then, 10 mL of $\mathrm{H}_{2} \mathrm{O}_{2}$ was added to check the $\mathrm{pO}_{2}$ probe. Due to the $\mathrm{O}_{2}$ production, the $\mathrm{pO}_{2}$ rose above the measuring range of the probe. Next, the aeration was started again, so that the $\mathrm{pO}_{2}$ adjusted quickly to $0 \%$. If necessary, the probe was recalibrated. Afterwards, $\mathrm{H}_{2} \mathrm{O}_{2}$ was pumped into the reactor. After a steady state of the temperature and the oxygen level was reached, the conditions were held for at least 15 minutes and a sample was taken to determine the current $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and therefore, the turnover (4.3). The sample was taken at the end of every steady state phase to prevent a falsification due to the air, which was pushed back to the sampling system for cleaning issues.

Figure 13: Experimental setup for the investigation of the mass transfer of oxygen supplied by the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ in the UniVessel ${ }^{\circledR}$ (5 L).

Then, the dilution rate was varied, to study the impact of different inflow rates on the dissolved oxygen concentration and their effect on the $\mathrm{k}_{\mathrm{L}}$. An example of the $\mathrm{pO}_{2}$ profile is given in the appendix in Figure 57.

The $\mathrm{k}_{\mathrm{L}} \mathrm{a}$, calculated as an absolute value, due to the inverted oxygen transfer, is calculable by the following equation

$$
\begin{equation*}
\left|k_{L} a\right|=\left|\frac{O T R}{c_{l}^{*}-c_{l}}\right| \tag{49}
\end{equation*}
$$

which can be substituted with the following equations (provided that an ideally mixed gas phase exists):

$$
\begin{gather*}
O T R=D \cdot c\left(H_{2} O_{2}\right)_{i} \cdot \frac{X}{100} \cdot \frac{1}{2}  \tag{50}\\
c_{l}^{*}=c_{g, o} \cdot H^{c c}  \tag{51}\\
c_{g, o}=\frac{c_{g, i} \cdot \dot{V}_{g, i}+O T R \cdot V}{\dot{V}_{g, o}}  \tag{52}\\
\dot{V}_{g, o}=\dot{V}_{g, i}+O T R \cdot V \cdot \frac{R \cdot T}{p} \tag{53}
\end{gather*}
$$

$$
c_{l}=\frac{p_{O_{2}}}{100} \cdot c_{s}
$$

| $c_{l}=\frac{p_{0_{2}}}{100} \cdot c_{s}$ | (54) |  |
| :--- | :---: | :---: |
| Oxygen concentration in the gas phase at the reactor outlet | $c_{g, o}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |
| Henry constant (dimensionless) | $\mathrm{H}^{c c}$ | $[-]$ |
| Oxygen concentration in the gas phase at the reactor inlet | $c_{g, i}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |
| Gas volume flow at the reactor inlet | $\dot{V}_{g, i}$ | $\left[\frac{L}{s}\right]$ |

| Gas volume flow at the reactor outlet | $\dot{V}_{g, o}$ | $\left[\frac{L}{s}\right]$ |
| :--- | :---: | :---: |
| Percentage dissolved oxygen saturation concentration in PBS medium | $p_{O_{2}}$ | $[\%]$ |
| Oxygen saturation concentration in PBS medium | $c_{s}$ | $\left[\frac{\text { mole }}{L}\right]$ |

An example calculation is given in the appendix (Table 15).

Finally, the $\mathrm{k}_{\mathrm{L}} \mathrm{a}$ was determined by means of the gassing-out method (Meusel et al., unpublished). At first, the dissolved oxygen was deaerated with nitrogen and subsequently aerated with air. Then, the kla was calculable with the help of the differential algorithm (equation (29)).

### 4.8 Scanning electron microscope

For studies concerning the catalytic activity $\mathrm{MnO}_{2}$ samples were analysed by a scanning electron microscope. The samples were sputtered with gold for 3 min (layer thickness 3-5 nm) and analysed with a scanning electron microscope (FEI Quanta 200F). The pictures were taken with an Everhart-Thornley-detector (secondary electron detector).

## Results and Discussion

### 5.1 Establishment of a $\mathrm{H}_{2} \mathrm{O}_{2}$ measuring method

The determination of the current hydrogen peroxide concentration is important for the calculation of the turnover in a continuous reactor. Therefore, an exact measurement of the consumption within the range of 0 to $99.5 \%$ of the stock solution is needed, which corresponds to a concentration of 0.05 to $9.81 \frac{\text { mole }}{L}$. The titrimetric approach, recommended in the literature (Vogel and Mendham, 2000; Dokuzovic, 2015), showed a very good correlation between the measured and the theoretical value. The highest average deviation from the expected concentration was $-2.08 \%$ at $2.45 \frac{\mathrm{~mole}}{\mathrm{~L}}$. The standard deviation was never above $0.12 \%$ and the coefficient of determination was 1.0 (Figure 14). Thus, these results show that the described method is valid for a quick and exact determination of the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration in the studied section.

Figure 14: Illustration of the titrimetric measured $\mathrm{H}_{2} \mathrm{O}_{2}$ concentrations and their related theoretical values.

### 5.2 Establishment of an appropriate catalyst for the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$

Since the degradation of $\mathrm{H}_{2} \mathrm{O}_{2}$ at standard conditions only takes place by the support of a catalyst, a suitable candidate had to be found. As already mentioned, the literature cites the enzyme catalase, the soluble iron nitrate $\left(\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}\right)$ and the insoluble pyrolusite $\left(\mathrm{MnO}_{2}\right)$ as possible compounds (3.3.1). Research was carried out about their stability, their possible range of concentrations, safety issues and their reaction kinetics in a scale of 0.1 L. Knowledge about the latter is useful for the design of the procedure in a continuous mode. Since the literature declares the reaction as first-order (3.3.2), an accurate determination of the pseudo reaction rate $\mathrm{k}^{\prime}$ is possible by batch experiments with different catalyst concentrations (equation (48)).

### 5.2.1 Catalase

The degradation of $\mathrm{H}_{2} \mathrm{O}_{2}$ by catalase ( $0.48 \mathrm{mg},>10,000 \frac{\text { units }}{\mathrm{mg}}$ ) followed as postulated a first order reaction kinetic (Reißmann, 2015) and led to a temperature increase of 13.8 K (Figure 15). However, the reduction from initially $1 \frac{\text { mole }}{L}$ was not complete and stopped after 42 minutes at a turnover of $84 \%$. This might be explained by a decrease of

Figure 15: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by catalase (initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration: $1 \frac{\text { mole }}{L}$ ).
the enzymatic activity by a time- or turnover-dependent inactivation of the enzyme. For further investigations of this phenomenon, experiments with different initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentrations were executed. An increase of the concentration to $1.5 \frac{\text { mole }}{L}$ engendered a consumption of 0.64 mole substrate in 50 minutes before the reaction stopped. After a feed of 0.48 mg fresh catalase ( $>10,000 \frac{\text { units }}{\mathrm{mg}}$ ) the degradation continued for 16.5 min and stopped again. During this interval 0.69 mole $\mathrm{H}_{2} \mathrm{O}_{2}$ was digested (Figure 16).

Figure 16: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by catalase (initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration: $1.5 \frac{\mathrm{~mole}}{\mathrm{~L}}$, Catalase Feed ( $4.8 \frac{\mathrm{mg}}{\mathrm{L}}$ ) after 72 min ).

The obtained temperature profile fit to the obtained hydrogen peroxide progression. During the first phase the temperature rose in 39 minutes by 11.1 K , while in the second phase an increase of 9.8 K in 8.5 minutes was observed. The timespan difference is explainable by the Arrhenius-equation:

| $k=B \cdot e^{\frac{-E_{A}}{R \cdot T}}$ |  |  |
| :--- | :--- | :--- |
| Pre-exponential factor | $B$ | $\left[\frac{1}{h}\right]$ |
| Activation energy | $E_{A}$ | $\left[\frac{J}{\text { mole }}\right]$ |

Since the reaction rate constant depends on the temperature, it was much quicker after the catalase feed due to the increased temperature while the released heat stayed almost the same.

Furthermore, the effect of a decreased start concentration ( $0.5 \frac{\mathrm{~mole}}{\mathrm{~L}}$ ) was examined (Figure 17). After 9 minutes the entire initial hydrogen peroxide was dissipated and a feed of fresh $\mathrm{H}_{2} \mathrm{O}_{2}$ to $1.0 \frac{\text { mole }}{L}$ led to a continuation of the reaction until it stopped again. 0.33 mole $\mathrm{H}_{2} \mathrm{O}_{2}$ was broken down. As before, the temperature curve showed a direct dependency to the turnover of the substrate.

Figure 17: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by catalase (initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration: $0.5 \frac{\text { mole }}{\mathrm{L}}, \mathrm{H}_{2} \mathrm{O}_{2}$ Feed ( $1 \frac{\text { mole }}{\mathrm{L}}$ ) after 22.5 min ).

The described results reinforced the assumption of dissipation and inactivation of catalase. In these batch experiments the enzyme transformed $0.17,0.13,0.14$ or, respectively, 0.18 mole substrate per applied mg enzyme. Afterwards, it was unable to continue the degradation. A modelling of the time depended enzyme- and $\mathrm{H}_{2} \mathrm{O}_{2}$ diminution was performed for the experiment shown in Figure 15 with the following differential equation taken as a basis:

$$
\begin{equation*}
\frac{d c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)}{d t}=-k^{\prime} \cdot c\left(\text { Catalase }_{\text {active }}\right) \cdot c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right) \tag{56}
\end{equation*}
$$

| $\frac{d\left(\text { Catalase }_{\text {active }}\right)}{d t}=-k^{\prime \prime} \cdot c\left(\right.$ Catalase $\left._{\text {active }}\right)$ |  |  |
| :--- | :--- | :--- |
| Concentration of active catalase | $c\left(\right.$ Catalase $\left._{\text {active }}\right)$ | $\left[\frac{\mathrm{mg}}{\mathrm{L}}\right]$ |
| Inactivation rate | $k^{\prime \prime}$ | $\left[\frac{1}{h}\right]$ |

Equation (56) represents the time dependent reduction of the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration, whereas equation (57) describes the inactivation of catalase. The Matlab (Mathworks) calculation (Figure 18) resulted in reaction rate velocities of $1.2 \frac{L}{h \cdot m g}$ for $\mathrm{k}^{\prime}$ and $3 \frac{1}{h}$ for $\mathrm{k}^{\prime \prime}$ (ode45 solver, least square algorithm, source code in the appendix). ${ }^{2}$ Since $50 \%$ of the incipiently catalase was inactivated after 15 minutes a high frequently feeding of fresh enzyme would be necessary. Furthermore, the exact inactivation kinetic was unknown. Therefore, this enzyme was not an appropriate catalyst for experiments in a continuous mode. Hence, other catalysts were tested on their potential.

[^1]

### 5.2.2 Iron nitrate

### 5.2.2.1 Reaction kinetic

As described above, $\mathrm{Fe}^{3+}$ is another possible catalyst for the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ (3.3.1.2) and can be applied e.g. as $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$-salt. The catalysis can undergo a radical chain reaction or a three-step process, where the iron changes its oxidation number from +III to +IV and back (3.3.1.2). Independent from the mechanism, the iron (+III) forms in water a complex with six water molecules, which is, due to the high charge-size-ratio, able to emit a proton (Hancock, 2015). The resulting complex gives the solution an amber colour (Marzzacco, 2015):

$$
\begin{gather*}
\mathrm{Fe}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}{ }^{3+} \leftrightarrow \mathrm{Fe}\left(\mathrm{H}_{2} \mathrm{O}\right)_{5} \mathrm{OH}^{2+}+\mathrm{H}^{+}  \tag{58}\\
\text {(colourless) } \\
\text { (amber) }
\end{gather*}
$$

The literature is split over the need of acidification of the $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution (Marzzacco, 2015; Brehm, 2015). Hence, the effect of $0.19 \frac{\mathrm{~mole}}{\mathrm{~L}} \mathrm{HNO}_{3}$ on a $1.5 \frac{\mathrm{~g}}{\mathrm{~L}} \mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution was
tested (Figure 19). These concentrations were recommended by Brehm. The curve progression showed a very slow decomposition for the acidified solution (0.4 \% turnover after 14 min ) while the pure $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution depicted a 70 -fold quicker reaction. The difference may be due to the chain breaking process by the interaction of two radicals, which is supported by protons and thus, at a low pH (Haber and Weiss, 1934). As described above, the pseudo reaction rate is exactly computable with equation (48) by batch experiments with different catalyst concentrations (5.2). Based on the obtained results, these studies were performed without $\mathrm{HNO}_{3}$ (Figure 19).

Figure 19: Profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ with and without $\mathrm{HNO}_{3}$.

### 5.2.2.2 Normalisation of the reaction rate

The reaction rate depends very strongly on the current temperature in the medium (equation (55)). Since the temperature rises during the experiment, the reaction rate changes as well. To approximately estimate the catalyst independent reaction rate $\mathrm{k}^{\prime}$ for the design of the continuous procedure, the reaction rate velocities were standardized with a temperature correction.

For this standardisation, at first, the reaction rate k has to be defined.

| $\qquad k_{i, i+1}=\ln \left(\frac{c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i+1}}{c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i}}\right) \cdot \frac{1}{t_{i+1}-t_{i}}$ |  |  |
| :--- | :--- | :--- |
| Average reaction rate for two adjacent measurement points | $k_{i, i+1}$ | $\left[\frac{1}{h}\right]$ |
| $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration at the measurement point $\mathrm{i}+1$ | $c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i+1}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |
| $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration at the measurement point i | $c\left(\mathrm{H}_{2} \mathrm{O}_{2}\right)_{i}$ | $\left[\frac{\mathrm{~mole}}{\mathrm{~L}}\right]$ |
| Time at the measurement point $\mathrm{i}+1$ | $t_{i+1}$ | $[\mathrm{~h}]$ |
| Time at the measurement point i | $t_{i}$ | $[\mathrm{~h}]$ |

The mean temperature is described by

$$
\bar{T}_{i, i+1}=\frac{T_{i}+T_{i+1}}{2}
$$

| Average temperature for two adjacent measurement points | $\bar{T}_{i, i+1}$ | $[K]$ |
| :--- | :--- | :--- |
| Temperature at the measurement point i | $T_{i}$ | $[\mathrm{~K}]$ |
| Temperature at the measurement point $\mathrm{i}+1$ | $T_{i+1}$ | $[\mathrm{~K}]$ |

To obtain a comparable k-value all measured reaction rates have to be normed to $30^{\circ} \mathrm{C}$. This is possible, by calculating the increase of the reaction rate, which is only caused by the elevated temperature.

$$
\begin{equation*}
\frac{k\left(\bar{T}_{i, i+1}\right)}{k\left(30^{\circ} C\right)}=\frac{B \cdot e^{-\frac{E_{A}}{R \cdot \bar{T}_{i, i+1}}}}{B \cdot e^{-\frac{E_{A}}{R \cdot(30 K+273,15 K)}}}=\bar{\kappa}_{i, i+1} \tag{61}
\end{equation*}
$$

| Standardisation factor | $\bar{\kappa}_{i, i+1}$ | $[-]$ |
| :--- | :--- | :--- |
| Reaction rate at $30^{\circ} \mathrm{C}$ | $k\left(30^{\circ} \mathrm{C}\right)$ | $\left[\frac{1}{h}\right]$ |
| Reaction rate at the temperature $\overline{\mathrm{T}}_{\mathrm{i}, \mathrm{i}+1}$ | $k\left(\bar{T}_{i, i+1}\right)$ | $\left[\frac{1}{h}\right]$ |

Although the pre-exponential factor B is unknown, the equation is solvable, because it can be condensed to

$$
\begin{equation*}
\frac{k\left(\bar{T}_{i, i+1}\right)}{k\left(30^{\circ} \mathrm{C}\right)}=\frac{e^{-\frac{E_{A}}{R \cdot \bar{T}_{i, i+1}}}}{e^{-\frac{E_{A}}{R \cdot(30 K+273,15 K)}}}=\bar{\kappa}_{i, i+1} \tag{62}
\end{equation*}
$$

Division of the measured reaction rate by the standardisation factor leads to the standardised reaction rate.

$$
\begin{gather*}
\frac{k\left(\bar{T}_{i, i+1}\right)}{\bar{\kappa}_{1, i+1}}=k_{i, i+1}\left(30^{\circ} \mathrm{C}\right)  \tag{63}\\
\hline \text { Standardised reaction rate } k_{i, i+1}\left(30^{\circ} \mathrm{C}\right) \quad\left[\frac{1}{h}\right]
\end{gather*}
$$

Since, for each pair of measurement points a reaction rate was determined, every obtained and standardised reaction rate has to be rated time-dependently.

| $\frac{1}{t_{0}-t_{\text {end }}} \cdot \sum_{i=1}^{n}\left(t_{i+1}-t_{i}\right) \cdot k_{i, i+1}\left(30{ }^{\circ} \mathrm{C}\right)=k_{\text {corrected }}$ |  |  |
| :--- | :--- | :--- |
| Corrected reaction rate | $k_{\text {corrected }}$ | $\left[\frac{1}{h}\right]$ |
| Time at the end of the measurement | $t_{\text {end }}$ | $[h]$ |
| Time at the beginning of the measurement | $t_{0}$ | $[h]$ |

An example calculation is given in the appendix in Table 12 and Table 13.

The standardised results were plotted against the corresponding catalyst concentration (Figure 20). Based on equation (48), the slope of the resulting linear equation (5.1 $\frac{L}{h \cdot g}$ ) describes the pseudo reaction rate $\mathrm{k}^{\prime}$. A clear proof was given for the postulated kinetic (equation (37) and (38)). Therefore, a dimensioning of continuous modes was possible with $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$.

Figure 20: Determination of $\mathrm{k}^{\prime}$ by comparison of several $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ concentrations and their related reaction rates.

### 5.2.2.3 $\mathbf{p H}$-dependency of iron nitrate

However, $\mathrm{Fe}^{3+}$ is very acidic, due to its large size, high charge and its electronegativity, which influence the acidity of a metal ion strongly (Table 3). A Fe $\left(\mathrm{NO}_{3}\right)_{3}$ solution with a concentration of $5 \frac{g}{L}$ has a pH of 2.3 without addition of $\mathrm{HNO}_{3}$. Due to safety reasons and material issues this was not acceptable. Investigations were carried out, to shift the pH to the neutral section without reducing its catalytic activity.

An increase of the pH to 7 with NaOH was not possible because the iron (+III) reacted with the hydroxide ions to an insoluble compound (solubility product: $2.79 \cdot 10^{-39} \frac{\mathrm{~mole}}{\mathrm{~L}^{4}}$ (Lide, 1998) before the solution reached a pH of 3 (Figure 21) (Holleman et al., 2007).

$$
3 \mathrm{NaOH}(\mathrm{aq})+\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}(\mathrm{aq}) \rightarrow 3 \mathrm{NaNO}_{3}(\mathrm{aq})+\mathrm{Fe}(\mathrm{OH})_{3}(s) \downarrow
$$

Figure 21: Influence of NaOH on the pH of a $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution $\left(5 \frac{g}{L}\right)$.

Table 3: Dependency of the ionic radius and the charge of metal ions on their $\mathrm{pK}_{\mathrm{a}}$ (Hancock, 2015).

|  | $\mathrm{Be}^{2+}$ | $\mathrm{Mg}^{2+}$ |  | $\mathrm{Ca}^{2+}$ |  | $\mathrm{Sr}^{2+}$ | $\mathrm{Ba}^{2+}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Ionic radius ( $\AA$ ) | 0.27 | 0.74 |  | 1.00 |  | 1.18 | 1.36 |
| pK a | 5.6 | 11.4 |  | 12.7 |  | 13.2 | 13.4 |
|  | $\mathrm{Na}^{+}$ |  | $\mathrm{Ca}^{2+}$ |  | $\mathrm{La}^{3+}$ |  | Th ${ }^{+}$ |
| Ionic radius ( A ) | 1.02 |  | 1.00 |  | 1.03 |  | 0.94 |
| $\mathrm{pK}_{\mathrm{a}}$ | 14.1 |  | 12.7 |  | 8.5 |  | 3.2 |

During the titration a colour change from a slight yellow to red-brown was visible (Figure 22). This shift is explainable by the change of the chemical formula due to the increased pH (Table 4).

Figure 22: Photographic illustration of the influence of NaOH on the pH of a $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution $\left(5 \frac{g}{L}\right)$. From left to right: $0,2.5,5.0,9.9,19.6,29.1,38.5,47.6 \frac{\mathrm{mmole}}{L} \mathrm{NaOH}$.

Table 4: Influence of the pH on the chemical formula and other properties of $\mathrm{Fe}^{3+}$ (Holleman et al., 2007; Hancock, 2015; Holdt, 2015)

| pH | Chemical formula | Colour |
| :---: | :---: | :---: |
| $<0$ | $\left.\left[\mathrm{Fe}\left(\mathrm{H}_{2} \mathrm{O}\right)_{6}\right)^{3+}\right]$ | Colourless $/$ pale <br> lilac |
| $0-2$ | $\left.\left[\mathrm{Fe}(\mathrm{OH})\left(\mathrm{H}_{2} \mathrm{O}\right)_{5}\right)^{2+}\right]$ and $\left.\left[\mathrm{Fe}(\mathrm{OH})_{2}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right)^{+}\right]$ | Yellow-brown |
| $2-3$ | $\left[\left(\mathrm{H}_{2} \mathrm{O}\right)_{4} \mathrm{Fe}(\mu-\mathrm{OH})_{2} \mathrm{Fe}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]^{++}$and |  |
| $\left[\left(\mathrm{H}_{2} \mathrm{O}\right)_{5} \mathrm{Fe}-\mathrm{O}-\mathrm{Fe}\left(\mathrm{H}_{2} \mathrm{O}\right)_{5}\right]^{4+}$ | Yellow-brown |  |
| $3-5$ | Multiple-core Isopolyoxo-Cations | Yellow-brown |
| $>5$ | $\mathrm{FeOH}_{3}$ | Red-brown |

To circumvent the formation of $\mathrm{Fe}(\mathrm{OH})_{3}$ during the pH increases, the use of $\mathrm{NH}_{3}$ instead of NaOH is not an option. Compared to $\mathrm{Fe}^{2+}$, where $\left[\mathrm{Fe}\left(\mathrm{NH}_{3}\right)_{6}\right]^{2+}$ emerges, no $\left[\mathrm{Fe}\left(\mathrm{NH}_{3}\right)_{6}\right]^{3+}$ and only $\mathrm{Fe}(\mathrm{OH})_{3}$ is formed. The reason for this is the low affinity of $\mathrm{Fe}^{3+}$ to
ammonia. However, EDTA (Ethylenediaminetetraacetic acid) is a potential chelating agent for $\mathrm{Fe}^{3+}$. As a sixtoothed-ligand it is able to form $\left[\mathrm{Fe}(E D T A)\left(\mathrm{H}_{2} \mathrm{O}\right)\right.$ ] (Ferric coordination number: 7 (similar to haemoglobin)) (Holleman et al., 2007).
A titration of NaOH to an EDTA-Fe $\left(\mathrm{NO}_{3}\right)_{3}$-solution $\left(5 \frac{g}{L} \mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}, 46 \frac{g}{L}\right.$ EDTA) showed the typical pH-progress of a multiple-protonic acid with several plateaus (probably due to the EDTA) (Figure 23). Compared to the $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$-solution without EDTA, only a slow pH increase was detected. Furthermore, precipitations were firstly perceived at a pH of 8.37 (Figure 24). Therefore, an adjustment of pH 7 was possible.

Figure 23: Influence of NaOH on the pH of an $\mathrm{EDTA}-\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution.

Figure 24: Photographic illustration of the influence of NaOH on the pH of an EDTA- $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution. From left to right: $0,65,149,231,310$ and $444 \frac{\text { mmole }}{L} \mathrm{NaOH}$.

However, the concentration of EDTA might be too high and hence, influence the catalytic activity. Thus, experiments with a decreased amount of EDTA were performed (Figure 25). However, smaller concentrations of EDTA than the initially one ( $46 \frac{g}{L}$ EDTA) led to an increased pH and precipitations (Figure 26).

Figure 25: Illustration of the influence of EDTA on the pH of a $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution $\left(5 \frac{g}{L}\right)$ with $123 \frac{\mathrm{mmol}}{\mathrm{L}} \mathrm{NaOH}$.

Figure 26: Photographical illustration of the influence of EDTA on the pH of a $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution $\left(5 \frac{g}{L}\right)$. From left to right: $0,8.8,17.5,26.3,35.1$ and $43.9 \frac{g}{L}$ EDTA with $123 \frac{\mathrm{mmol}}{\mathrm{L}} \mathrm{NaOH}$.

However, the incipiently problem of a too low pH was solved with an EDTA concentration of $46 \frac{g}{L}$ for a $5 \frac{g}{L} \mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ solution. Next, the decomposition activity of [ $\left.\mathrm{Fe}(E D T A)\left(\mathrm{H}_{2} \mathrm{O}\right)\right]$ was investigated. A 0.1 L batch experiment resulted in a decrease of the initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration (Figure 27). Therefore, $\left[\mathrm{Fe}(E D T A)\left(\mathrm{H}_{2} \mathrm{O}\right)\right]$ was still able to
decompose hydrogen peroxide. The pH ranged from 7.2 in the beginning to 7.6 in the end and was thus, in the required scope. However, the reaction was slower (compared to the obtained results with $5 \frac{g}{L} \mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ and without EDTA) and the catalyst seemed to be inactivated by time, because the temperature profile showed no further heat production and according to this, no further decomposition. Merely $0.72 \frac{\text { mole }}{L}$ was converted to $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{O}_{2}$ after 80 minutes, which comply with $48 \%$ of the initial value. In addition to that, the exact reaction kinetic for these settings was still unclear.

Figure 27: Comparison of the temperature profile and the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration of a $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$-solution with and without EDTA in a scale of 0.1 L processed in batch mode.

### 5.2.3 Manganese-(IV)-oxide

### 5.2.3.1 Reaction kinetic

Due to the quick inactivation of catalase and the safety issues of $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ manganese dioxide was studied for its potential concerning a steady and safe decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$. Just as the other catalysts, the breakdown by $\mathrm{MnO}_{2}$ depicted a first order kinetic (Figure 28), which is also referred in the literature (Akhtar et al., 2012). As distinguished from catalase, the reaction led to a complete decline of $\mathrm{H}_{2} \mathrm{O}_{2}$ and thus, showed no time depended inhibition or inactivation in the range of $5.4 \frac{g \mathrm{MnO}_{2}}{\text { mole } \mathrm{H}_{2} \mathrm{O}_{2}}$ (Figure 29) to $0.1 \frac{g \mathrm{MnO}_{2}}{\text { mole } \mathrm{H}_{2} \mathrm{O}_{2}}$ (Figure 30). The latter did not display an entire turnover during a measuring time of 20.6 hours due to the smaller amount of $\mathrm{MnO}_{2}$, but followed as well a first order kinetic. The low reaction rate is explainable as well by the temperature profile of the liquid. It only depicted an increase of 2.7 K . During the night, the solution cooled down (3.8 K under the initial temperature), which further decreased the reaction rate.

Figure 28: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by $\mathrm{MnO}_{2}\left(0.86 \frac{g \mathrm{MnO}}{L}\right.$, $0.6 \frac{g \mathrm{MnO}_{2}}{\text { mole } \mathrm{H}_{2} \mathrm{O}_{2}}$ ).

Figure 29: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by $\mathrm{MnO}_{2}\left(8.08 \frac{g \mathrm{MnO}_{2}}{L}\right.$, $5.4 \frac{g \mathrm{MnO}_{2}}{\text { mole } \mathrm{H}_{2} \mathrm{O}_{2}}$ ).

Figure 30: $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration and temperature profile of the $\mathrm{H}_{2} \mathrm{O}_{2}$ decomposition by $\mathrm{MnO}_{2}\left(0.10 \frac{g M n O_{2}}{L}\right.$, $\left.0.1 \frac{g \mathrm{MnO}_{2}}{\text { mole } \mathrm{H}_{2} \mathrm{O}_{2}}\right)$.

Nevertheless, an inactivation, similar (but slower) to the one observed with catalase, should be kept in mind. Martin mentioned a deactivation but did not describe this further (Martin, 1996). In this case, it was difficult to give evidence for that, due to the temperature curve and the related changing reaction rate.

Similar to $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$, the resulted decomposition profiles were normalised. However, this standardisation gives only a rough estimation, because the activation energy ( $\mathrm{E}_{\mathrm{A}}$ ) is needed. The literature is unclear about $\mathrm{E}_{\mathrm{A}}$ for the $\mathrm{MnO}_{2}$ catalysed reaction and states two different values ( 58 and $82 \frac{\mathrm{~kJ}}{\text { mole }}$ ). Hence, an average activation energy of $70 \frac{\mathrm{~kJ}}{\mathrm{~mole}}$ was assumed. Nevertheless, this should refine the measured results and be sufficient for a first dimensioning.
The corrected reaction rates were plotted against their corresponding catalyst concentration and a linear regression was made (Figure 31). The slope of the straight line represents the pseudo reaction rate $\mathrm{k}^{\prime}$. In this case it was $1.4 \frac{\mathrm{~L}}{\mathrm{~h} \cdot \mathrm{~g}}$.

Figure 31: Determination of $\mathrm{k}^{\prime}$ by comparison of several $\mathrm{MnO}_{2}$ concentrations and their related reaction rates.

However, the data from $8.08 \frac{g}{L} \mathrm{MnO}_{2}$ showed a high deviation compared to the other measurements $\left(\mathrm{k}^{\prime}=5.9 \frac{L}{h \cdot g}\right)$. A possible explanation for this phenomenon is the very short time of the reaction (the substrate was decomposed in less than 1.7 min ). Therefore, less measuring points were possible during this time span. Furthermore, the sampling was difficult due to strong foam formation, not only in the beaker but also in the pipette tip. According to that, precise pipetting was not possible. However, the results of the other measurements showed a strong linear relationship, which allowed a first assessment of a continuous reactor, by which a constant heat production is possible.

### 5.2.3.2 Disposal strategy

Since $\mathrm{MnO}_{2}$ cannot be just disposed to the sewage due to environmental regulations, a strategy of waste management was established. Reducing the amount of waste is possible by filtration of the insoluble solid material. The choice of the utilised membrane depends on the size of the $\mathrm{MnO}_{2}$ particles. Therefore, a light microscopically investigation was executed. It revealed that the majority of the particles were bigger than $30 \mu \mathrm{~m}$ (Figure 32), wherefore a membrane with a pore wideness of $0.2 \mu \mathrm{~m}$ is capable to hold them back.

With a single-use Büchner funnel (180C6, $0.22 \mu \mathrm{~m}$ PES membrane, Sartorius) plugged to a vacuum pump, a complete separation of the $\mathrm{MnO}_{2}$ was possible (Figure 53, appendix). Furthermore, a multi-use Büchner funnel with a Microsart polyethersulfone-(PESU)membrane ( $0.2 \mu \mathrm{~m}$ ) was checked for its potential (Figure 54, appendix). Exactly like the single-use solution, the manganese oxide was separated completely. The results of a scanning electron microscopically analysis supported the assumption, that the pore wideness of the PESU-membrane was narrow enough, to hold the $\mathrm{MnO}_{2}$ particles back (Figure 33).

Figure 32: Light microscope picture of $\mathrm{MnO}_{2}$ (400-fold-optical enlargement).

Since the filter area of the multi-use device was smaller compared to the single-use one, the possible amount of separated $\mathrm{MnO}_{2}$ was less. On the other side, the costs of the membrane for the multi-use Büchner funnel were estimated as much lower than the costs for the single-use device.

Figure 33: Electron-scan microscope picture of $\mathrm{MnO}_{2}$ on a Microsart PESU-membrane ( $0.2 \mu \mathrm{~m}$ ).

However, both disposal strategies are only suitable for relatively small volumes and volume flows of the $\mathrm{MnO}_{2}$ suspension and a constant refilling of the Büchner funnel is necessary. In addition, it is not possible to prevent fine dust formation from the dried filter cake. Hence, another solution had to be found to realise higher flows with easier handling and without safety issues. On this account, a filtration capsule (Sartopore 2
( $0.45+0.2 \mu \mathrm{~m}$ ), PESU-membrane) in combination with a pump (Watson Marlow 520) was tested and found to be appropriate (Figure 55, appendix). No residues were found in the filtrate just like in the experiments made before. Additionally, in contrast to them, a sealing of the tubes before and after the filtration capsule (e.g. with the BioSealer (Sartorius)) was possible, which implies a safe locking from the ambient air. As mentioned before, this is important, because a whirl up should be prevented due to fine dust formation and would not be possible for the filter in the Büchner funnel. For the sealing, a special tubing material was added (C-flex), which is not pumpable.

### 5.2.4 Conclusion

Three different catalysts were studied for their potential of decomposing $\mathrm{H}_{2} \mathrm{O}_{2}$ in a continuous reactor. Catalase, an enzyme found e.g. in the liver, was excluded, due to its quick inactivation. In contrast to that, $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ showed no change in the reaction rate. However, it was found as inappropriate, due to its low pH. A complexation with EDTA and a subsequent increase of the pH by NaOH led to a strong decrease of the reaction rate.

The third studied catalyst was $\mathrm{MnO}_{2}$. Similar to iron nitrate the reaction rate did not decrease over time in the batch experiments. Since it was investigated in PBS-buffer, the pH was in a neutral range. A possible problem can be the washing out effect of the catalyst in a continuous reactor. A permanent addition of $\mathrm{MnO}_{2}$ is not practicable, since it is not dissolved and quickly sediments. In Table 5 the pros and cons of the studied catalysts are summarized. On these grounds the continuous experiments were performed with $\mathrm{MnO}_{2}$.

Table 5: Advantages and disadvantages of possible catalysts for the digestion of $\mathrm{H}_{2} \mathrm{O}_{2}$.

| Catalyst | pH | Kinetic | Inactivation <br> detected in <br> batch mode | Type of <br> catalysis | Miscellaneous |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Catalase | 7 | Unknown | Yes | Biological | Expensive |
| $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ | $\sim 2$ | Known | No | Homogenous | $/$ |
| EDTA-Fe $\left(\mathrm{NO}_{3}\right)_{3}$ | $\sim 7$ | Unknown | No | Homogenous | Very slow <br> reaction |
| $\mathrm{MnO}_{2}$ | 7.4 | Known | No | Heterogeneous | Fine dust <br> formation |

### 5.3 Establishment of a continuous heat and oxygen production method

### 5.3.1 Studies concerning the steady state regarding temperature and quantity of substance

One of the major advantages of a continuous procedure is the simplified calculation of the specific heat transfer coefficient (UA), the volumetric mass transfer coefficient ( $\mathrm{k}_{\mathrm{L}}$ ) and different kinetic parameters like the reaction rate during the stationary phase. This phase is defined by no time-depended change, neither of the temperature, nor the concentration. In case of a varying volume (e.g. due to vaporizing or a decreased outflow out of the system caused by sucking of bubbles formed in the medium) instead of the concentration, the amount of substance has to be taken into account and will not vary.

During the steady state, a stable turnover lower than 100 percent is needed, because the calculation of kinetic parameters like the activation energy ( $\mathrm{E}_{\mathrm{A}}$ ), the pre-exponential factor (B) and the catalyst-independent pseudo reaction rate (k') are based on experiments with various turnovers. If the difference between them is too small, big mistakes will occur and the results would be inaccurate.

Since $\mathrm{MnO}_{2}$ was shown to be an appropriate catalyst due to stability and disposal, a continuous process was established with this compound, to enable a constant heat and oxygen release for the determination of UA and $\mathrm{k}_{\mathrm{L}}$. Since only two relatively different references for $E_{A}$ were found in the literature (5.2.3), the already calculated reaction rate ( $\mathrm{k}^{\prime}$ ) should be verified, because an inaccuracy might falsify $\mathrm{k}^{\prime}$ relatively strong (equation (55)).

The first experiment in a scale of 0.1 L depicted an initial slope of $\mathrm{H}_{2} \mathrm{O}_{2}$, which seemed to tend towards the steady state concentration. However, after 80 minutes the slope of $\mathrm{H}_{2} \mathrm{O}_{2}$ reached its minimum and the amount of hydrogen peroxide ran through (Figure 34), whereas the temperature reached a maximum of $32.1^{\circ} \mathrm{C}$. Therefore, the stationary phase was not achieved. The observed behaviour might be explained by the long span, which increased more and more the washing out effect of the catalyst. In reference to the theoretically calculated and illustrated $\mathrm{MnO}_{2}$ concentration, it became apparent, that the catalyst concentration already reduced from $0.50 \frac{g}{L}$ to $0.42 \frac{\mathrm{~g}}{\mathrm{~L}}$. Probably due to the time-depended increase of this effect or a possible inactivation, it was not possible, to reach a stationary phase.

Figure 34: Temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.1 L processed in continuous mode $\left(\mathrm{MnO}_{2}\right.$ start concentration: $0.50 \frac{g}{\mathrm{~L}}$, dilution rate: $0.1 \frac{1}{h}$ ).

To shorten the long transient oscillation, the initial amount of $\mathrm{H}_{2} \mathrm{O}_{2}$ was increased to reach the saturation condition quicker (Figure 35). However, the great amount of

Figure 35: Illustration of the influence of an initial $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration on the temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.1 L processed in continuous mode ( $\mathrm{MnO}_{2}$ start concentration: $0.50 \frac{\mathrm{~g}}{\mathrm{~L}}$, dilution rate: $0.1 \frac{1}{h}$ ).
hydrogen peroxide led to a higher reaction velocity and, as a consequent to a higher heat release, which in turn supported the combustion. The progression converged with the results sighted before.

Due to the fact, that increased dilution rates led to a quicker increase of the amount of substance (Figure 36), a process cascade with a higher initial dilution rate ( $0.8 \frac{1}{h}(0-12.5 \mathrm{~min})$ and $0.1 \frac{1}{h}(12.5-182 \mathrm{~min})$ ) was performed (Figure 37). The desired quantity of substance was achieved in the beginning by this method; however, the catalyst was probably washed out in the same way. Therefore, the process was shortened but the stationary phase was not reached again.

Figure 36: Illustration of the influence of different dilution rates ( $0.1 \frac{1}{h}$ and $0.25 \frac{1}{h}$ ) on the temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.1 L processed in continuous mode ( $\mathrm{MnO}_{2}$ start concentration: $0.50 \frac{\mathrm{~g}}{\mathrm{~L}}$ ).

Figure 37: Illustration of the influence of a dilution rate profile on the temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.1 L processed in continuous mode.

The theoretical coherence of the catalyst concentration and the turnover was plotted in Figure 38 according to equation (43). This correlation made clear, that over a wide range ( $>1 \frac{g}{L}$ ) a decrease of the concentration has no impact and thus, the washing out should not affect the turnover and the amount of substance in the stationary stage. Below this threshold of $1 \frac{g}{L}$, a slight decrease leads to a large decline. Nevertheless, it would not be reasonable to use too high amounts of $\mathrm{MnO}_{2}$, due to the effort for the disposal. Furthermore, larger quantities of $\mathrm{H}_{2} \mathrm{O}_{2}$ would be associated for a high, but not complete turnover. This would demand high dilution rates and beside that, it would increase the washing out effect again.

Figure 38: Theoretical coherence of the $\mathrm{MnO}_{2}$ concentration and the linked turnover ( $\mathrm{D}=0.1 \frac{1}{h^{\prime}}, \mathrm{k}^{\prime}=1.4 \frac{L}{\mathrm{~h} \cdot \mathrm{~g}}$ ).

Based on this, higher catalyst concentrations $\left(0.86,1.50\right.$ and $4.00 \frac{g}{L}$ ) were examined to study this relationship (Figure 39). With these settings, a stationary phase was

Figure 39: Illustration of the influence of different $\mathrm{MnO}_{2}$ concentrations on the temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.1 L processed in continuous mode ( $\mathrm{D}=$ $0.1 \frac{1}{h}$ ).
observed for $4.00 \frac{g}{L} \mathrm{MnO}_{2}$ (labelled orange). Merely the temperature profile showed its maximum shifted (after 250 min ) and besides oscillated. The reason for this shifting was the required time for the medium to heat up, and can be solved by a temperature regulation. Since this was not possible in the utilised 250 mL beaker, a process transfer to the UniVessel ${ }^{\circledR}$ (2 L) with a heating jacket was performed.

Furthermore the $\mathrm{MnO}_{2}$ rinsing needs to be prevented, because the decreasing of the catalyst concentration over time results in a constantly changing steady state concentration. Wirges solved the problem with a continuous addition of the catalyst (Wirges, 1977). Since he used the soluble $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$, instead of the insoluble $\mathrm{MnO}_{2}$, he balanced this rinsing effect. For a $\mathrm{MnO}_{2}$ suspension this runs into difficulties, because the particles sediment quickly. Therefore, an evenly feeding is not possible. A feasible solution is a filtration probe at the medium outlet instead of a common tube. As mentioned before (5.2.3.2) a $0.2 \mu \mathrm{~m}$ membrane withheld the $\mathrm{MnO}_{2}$ particles reliably.

### 5.3.2 Prevention of the washing-out effect

To stop the steady rinsing of $\mathrm{MnO}_{2}$ from the reactor, a filtration probe was manufactured out of a Microsart PESU-Membrane ( $0.2 \mu \mathrm{~m}$ ), a seal ring and a plastic case (Figure 40). The probe was plugged to the outlet tubing, fixed at the sleeve of the temperature probe and directed towards the stirrer to prevent the forming of a filter cake and therefore, the clogging of the filter.

Figure 40: Filtration probe with a Microsart PESU-membrane

To test the device for its potential a $\mathrm{MnO}_{2}$ suspension ( $4.00 \frac{g}{L}$ ) was filled into the 2 litre vessel. The reactor was operated like before in the continuous experiments, merely no $\mathrm{H}_{2} \mathrm{O}_{2}$ was added and the dilution rate was set to $0.3 \frac{1}{h}$ to make sure that no blocking of the filter occurs for higher mass flows. Since the filtrate was clear, the test showed that no $\mathrm{MnO}_{2}$ passed the membrane. On top of this, the flow rate only deviated about $1 \%$ during more than 2.5 hours of examination and did not decrease over time (Figure 41). Therefore, the suction was not significantly influenced by the attached filtration probe.

Figure 41: Temporal course of the delivered volume with the filtration probe for the validation of the unresisted pump capacity ( $D=0.3 \frac{1}{h}$ ).

After the experiment, a slight filter cake was found on the membrane. However, it can be removed mainly by rinsing with RO-water (Figure 42). Subsequently, the filter was reusable and applicable.

Figure 42: Filtration probe before (left) and after rinsing (right).

By the use of the filtration probe, lower catalyst concentrations are possible and therefore, a turnover less than 100 percent without the threat of unstable hydrogen peroxide concentrations caused by the dilution of the catalyst. As described above (5.3.1) these states are needed, because the calculation of many kinetic parameters are based on experiments with different balance conditions. Sufficient accuracy is only given for significant differences between them. The following experiments with the filtration probe (and 0.1 or, respectively, $0.5 \frac{g}{L} \mathrm{MnO}_{2}$ ) were carried out with 0.35 L in the UniVessel ${ }^{\circledR}(2 \mathrm{~L})$. This small scale was chosen, to minimise the $\mathrm{H}_{2} \mathrm{O}_{2}$ consumption and $\mathrm{MnO}_{2}$ waste production in this early phase of development. The agitation was set to 500 rpm , because higher speeds led to stronger squirting at this small amount of medium. The temperature was set to $30^{\circ} \mathrm{C}$ instead of the common used temperature for fermentations ( $37^{\circ} \mathrm{C}$ ) to shorten the initial heating up time span. For comparisons with results from fermentations, subsequent measurements at $37{ }^{\circ} \mathrm{C}$ and 1500 rpm are recommended.

Despite of the filtered sampling and the additional temperature regulation, no steady state was achieved. After approximately 80 minutes a buckling was observed and a linear increasing of the amount of $\mathrm{H}_{2} \mathrm{O}_{2}$ occurred (Figure 43). The stopping of the continuous inflow of the hydrogen peroxide and the outflow of the medium after 260 minutes, (thus, switching in batch mode) resulted for the suspension with $0.5 \frac{\mathrm{~g}}{\mathrm{~L}} \mathrm{MnO}_{2}$ in a slight decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$. Compared to previous studies, the reaction velocity was
strongly decreased. Only 0.18 mole $\mathrm{H}_{2} \mathrm{O}_{2}$ were decomposed in 13 minutes (initial concentration $2.0 \frac{\text { mole }}{L}$ ) with $0.5 \frac{g}{L} \mathrm{MnO}_{2}$, whereas 0.84 mole $\mathrm{H}_{2} \mathrm{O}_{2}$ were decomposed in 12.8 minutes (initial concentration $1.5 \frac{\text { mole }}{L}$ ) with $0.86 \frac{g}{L} \mathrm{MnO}_{2}$ in earlier experiments. As already mentioned, an inactivation of $\mathrm{MnO}_{2}$ for long-term experiments was brought up in the literature (Martin, 1996). However, no further investigation has been made and no more data has been published. That was why studies concerning the catalytic activity of $\mathrm{MnO}_{2}$ were executed.

Figure 43: Temporal course of the temperature and the amount of substance of $\mathrm{H}_{2} \mathrm{O}_{2}$ in a scale of 0.35 L (UniVessel ${ }^{\circledR} 2 \mathrm{~L}$ ) processed in continuous, temperature regulated mode ( $30^{\circ} \mathrm{C}$ ) with a filtration probe and different $\mathrm{MnO}_{2}$ concentrations.

### 5.3.3 Investigations concerning the catalytic activity of $\mathrm{MnO}_{2}$

In preliminary experiments with low amounts of substrate no inactivation or decrease of the $\mathrm{MnO}_{2}$ catalytic activity were observed (5.2.3.1). However, the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration did not stop to increase in continuous mode. Since the prevention of the rinsing effect did not solve this problem, an inactivation of the catalyst may be present. To understand this phenomenon a repeated fed-batch was performed. $0.5 \frac{g}{\mathrm{~L}} \mathrm{MnO}_{2}$ was added to 350 mL of a $0.88 \frac{\mathrm{~mole}}{L} \mathrm{H}_{2} \mathrm{O}_{2}$ solution and the decreasing concentration of hydrogen peroxide was measured. Every 90 minutes fresh $\mathrm{H}_{2} \mathrm{O}_{2}$ was supplied so that the initial concentration was reached again. During the whole process, the temperature was regulated and set to
$30^{\circ} \mathrm{C}$ (Figure 44). The experimental conditions ( $500 \mathrm{rpm}, 30^{\circ} \mathrm{C}$ and 350 mL ) were chosen due to the reasons already mentioned in chapter 5.3.2.

The behaviour of the hydrogen peroxide concentration revealed an ongoing retardation of the reaction velocity (Figure 45). During the first and the second feed, the $\mathrm{MnO}_{2}$ decomposed only $65 \%$ and, respectively, $47 \%$ of the amount degraded in the initial batch. Beyond that, the swings of the temperature profiles got narrower after each feed, which leads to the assumption, that less heat was produced and hence, the reaction did not take place in the same strength like before. Compared to the experiments made before in the 0.1 L scale, this time the temperature was kept constant and had therefore no influence on the reaction (except the first minutes after the feeds where the temperature had to settle again). Since Martin wrote that salts do not affect the activity of $\mathrm{MnO}_{2}$, the inactivation has to depend on time or on the decomposed amount of substance (Martin, 1996). Scanning electron microscopically analysis showed no difference in the surface structure of fresh and inactivated $\mathrm{MnO}_{2}$ (Figure 56, appendix). The obtained inactivation effect reveals the reason for the unachievable steady-state conditions both in small scale ( 0.1 L , unregulated temperature) and in bigger scale ( 0.35 L , regulated temperature). The inactivation effect seems to be much stronger than the rinsing effect because, independent of the utilisation of the filtration probe, the same decrease of the reaction rate occurred again.

Figure 44: Temporal course of the temperature and the $\mathrm{H}_{2} \mathrm{O}_{2}$ concentration of a repeated fed-batch in a scale of 0.35 L .

Figure 45: Illustration of the reaction rate in connection with the decomposed amount of substance.

### 5.3.4 Development of a feeding strategy to overcome $\mathrm{MnO}_{2}$ inactivation

Generally, kinetic parameters like the activation energy ( $\mathrm{E}_{\mathrm{A}}$ ), the pre-exponential factor and the pseudo reaction rate ( k ) are determinable by several experiments with various turnovers (caused by varied dilution rates) or, respectively, diverse temperatures in the stationary phase. Then the calculation can be made by equation (65), (66) and (67) (derived by equation (43)).

$$
\begin{equation*}
E_{A}=R \cdot \ln (2) \cdot \frac{T_{1} \cdot T_{2}}{T_{1}-T_{2}} \tag{65}
\end{equation*}
$$

Temperature in experiment number $1 \quad T_{1} \quad[K]$

Temperature in experiment number $2 \quad T_{2} \quad K$

$$
\begin{equation*}
B=\frac{k^{\prime} \cdot c(C A T)}{e^{\frac{E_{A}}{R \cdot T}}} \tag{66}
\end{equation*}
$$

$$
\begin{equation*}
k^{\prime}=\frac{X \cdot D}{c(C A T) \cdot(1-X)} \tag{67}
\end{equation*}
$$

However, up to this point no steady state was achieved. The unknown inactivation kinetic of $\mathrm{MnO}_{2}$ made it difficult to feed the exact needed amount during a process to hold not only a specific concentration but as well a certain catalytic activity and consequently, a certain turnover. On that score it had to be resigned to identify the exact kinetic parameters of the process. However, investigations regarding the heat and mass transfer can be still performed. At very high catalyst concentrations the dilution and inactivation effects are no issue (Figure 38). To overcome a possible drop of the turnover, periodical catalyst feeds are recommendable, which consider both mentioned effects. According to this, a turnover of almost 100 \% during the whole process is expected and the delivered amount of heat is rigorously calculable.
In a scale of 0.35 L these assumptions were tested. Because preliminary experiments showed a steady state for $4 \frac{g}{L} \mathrm{MnO}_{2}$ and a dilution rate of $0.1 \frac{1}{h}$ (Figure 39), the trial was executed with higher $\mathrm{MnO}_{2}$ concentration ( $6 \frac{g}{L}$ ) in the beginning to enable analyses with higher dilution rates. To prevent a decrease of the turnover during the measurement by inactivation and rinsing, $3 \frac{g}{L} \mathrm{MnO}_{2}$ were fed every 60 minutes. During the entire procedure the estimated progression was detected in the presumed way. The turnover only fluctuated between 99.2 and 99.4 \%. The same experimental setting in a bigger scale ( 1 L medium in the UniVessel ${ }^{\circledR}$ ( 2 L ) and 3.5 L medium in the UniVessel ${ }^{\circledR}$ (5 L) ) resulted in very similar measurements. The turnover was always between 99.0 and $99.4 \%$ and the scale-up was therefore successful. Since two feeds are applied, three measurements of the $\mathrm{H}_{2} \mathrm{O}_{2}$ turnover and the temperature of the cooling water are possible in the steady states after 0,60 and 120 minutes.

### 5.3.5 Cost calculation

The higher recommended amount of $\mathrm{MnO}_{2}$ leads to higher costs of the whole process. Since a standard method should be cheap, a cost calculation for the catalyst and $\mathrm{H}_{2} \mathrm{O}_{2}$ was made (Table 6 - Table 8). The favoured feeding strategy of $\mathrm{MnO}_{2}$ resulted in costs up
to 23.52 € per execution in a 10 L bioreactor. In addition, the costs for the PBS-Buffer should be kept in mind.

Table 6: Cost calculation of $\mathrm{MnO}_{2}$ with a total usage of $12 \frac{g_{L}}{L}$.

| Volume of the <br> bioreactor [L] | Needed amount of <br> $\mathrm{MnO}_{2}$ for 10 <br> executions $[\mathrm{kg}]$ | Recommended <br> $\mathrm{MnO}_{2}$ container $[\mathrm{kg}]$ | Average costs per <br> execution |
| :---: | :---: | :---: | :---: |
| 1 | 0.12 | 0.25 | $2.99 €$ |

### 5.4 Determination of procedurally parameters in the UniVessel ${ }^{\circledR}$ (5 L)

The newly developed technique for the determination of the heat and mass transfer showed a constant heat and oxygen production in preliminary experiments (5.3.4). To prove its reliability, it was compared with conventional approaches. In case of the heat transfer, a stationary power input by an electrical calibration heater was applied. Furthermore, the oxygen transfer was studied in addition to the $\mathrm{H}_{2} \mathrm{O}_{2}$ technique with the dynamic gassing-out method.

### 5.4.1 Determination of UA

There are various sources and sinks of heat flows in a bioreactor (Figure 46) (Storhas, 1994; Regestein, 2012). The system can be described by two balancing spaces, which are related with each other by the heat flow $\dot{Q}_{\text {Jacket }}$ (highlighted in orange).

Figure 46: Schematic representation of possible heat flows in a bioreactor. In particular, the decomposition of $\mathrm{H}_{2} \mathrm{O}_{2}$ is stated as a model reaction for the heat production by a chemical or microbial reaction. The system is divided in two sections (balancing space 1: the reactor (grey), balancing space 2: the double jacket (blue)).

The first balancing space (the inner part of the reactor) can be described with the following balances:

| Power input by the reaction to the reactor | $P_{\text {Reaction }}$ | [W] |
| :---: | :---: | :---: |
| Power input by the stirrer to the reactor | $P_{\text {Stirrer }}$ | [W] |
| Heat flow by the inflowing $\mathrm{H}_{2} \mathrm{O}_{2}$ | $\dot{Q}_{\mathrm{H}_{2} \mathrm{O}_{2}, \text { in }}$ | [W] |
| Heat flow from the reactor to the jacket | $\dot{Q}_{\text {Jacket }}$ | [W] |
| Heat flow by the evaporating oxygen | $\dot{Q}_{\text {Evaporation }}$ | [W] |
| Heat flow from the reactor through the lid to the environment | $\dot{Q}_{l o s s} 1$ | [W] |
| Heat flow by the outflowing medium | $\dot{Q}_{\text {Medium,out }}$ | [W] |

| Reaction enthalpy | $\Delta H_{R}$ | $\left[\frac{\mathrm{J}}{\mathrm{mole}}\right]$ |
| :---: | :---: | :---: |
| Inflowing volume flow rate | $\dot{V}_{E}$ | $\left[\frac{L}{S}\right]$ |
| Amount of rotations of the stirrer per time | $N$ | $\left[\frac{1}{s}\right]$ |
| Torque | $M_{t}$ | $[N \cdot m]$ |
| Newton number | $N e$ | [-] |
| Density | $\rho$ | $\left\lceil\frac{k g}{L}\right]$ |
| Diameter of the stirrer | $d$ | [m] |
| Mass flow of the inflowing $\mathrm{H}_{2} \mathrm{O}_{2}$ | $\dot{m}_{\mathrm{H}_{2} \mathrm{O}_{2}}$ | $\left[\frac{\mathrm{kg}}{\mathrm{s}}\right]$ |
| Specific heat capacity of $\mathrm{H}_{2} \mathrm{O}_{2}$ | $c_{p, \mathrm{H}_{2} \mathrm{O}_{2}}$ | $\left[\frac{J}{K \cdot k g}\right]$ |
| Temperature of the environment | $T_{\text {Environment }}$ | [K] |
| Temperature of the reactor | $T_{\text {Reactor }}$ | [K] |
| Temperature of the outflowing cooling water | $T_{\text {Jacket,out }}$ | [K] |
| Mass flow of the evaporating $\mathrm{O}_{2}$ | $\dot{m}_{O_{2}}$ | $\left[\frac{\mathrm{kg}}{\mathrm{s}}\right]$ |
| Specific heat transfer coefficient for the reactor lid | $U A_{2}$ | $\left[\frac{W}{K}\right]$ |
| Mass flow of the outflowing medium | $\dot{m}_{\text {Medium }}$ | $\left\lceil\frac{\mathrm{kg}}{\mathrm{s}}\right]$ |
| Specific heat capacity of the medium | $c_{p, \text { Medium }}$ | $\left[\frac{J}{K \cdot k g}\right]$ |

In addition to that, the heat balance equation in the jacket (balancing space 2) comprises by:

$$
\begin{equation*}
\dot{Q}_{\text {Jacket,in }}+\dot{Q}_{\text {Jacket }}=\dot{Q}_{\text {loss } 2}+\dot{Q}_{\text {Jacket,out }} \tag{76}
\end{equation*}
$$

Heat flow by the inflowing cooling water $\quad \dot{Q}_{\text {Jacket,in }} \quad[W]$

Heat flow from the jacket chamber to the environment $\dot{Q}_{\text {loss } 2} \quad[W]$

Heat flow by the outflowing cooling water $\quad \dot{Q}_{\text {Jacket,out }} \quad[W]$

The enumerated heat flows can be specified by:

$$
\begin{equation*}
\dot{Q}_{\text {Jacket,in }}=\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot T_{\text {Jacket,in }} \tag{77}
\end{equation*}
$$

$$
\begin{equation*}
\dot{Q}_{\text {loss } 2}=U A_{3} \cdot\left(T_{\text {Jacket,out }}-T_{\text {Environment }}\right) \tag{78}
\end{equation*}
$$

$$
\begin{equation*}
\dot{Q}_{\text {Jacket,out }}=\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot T_{\text {Jacket,out }} \tag{79}
\end{equation*}
$$

| Mass flow of the cooling water | $\dot{m}_{\mathrm{H}_{2} \mathrm{O}}$ | $\left[\frac{\mathrm{kg}}{\mathrm{s}}\right]$ |
| :--- | :--- | :--- |
| Specific heat capacity of water | $c_{p, \mathrm{H}_{2} \mathrm{O}}$ | $\left[\frac{\mathrm{J}}{\mathrm{K} \cdot \mathrm{kg}}\right]$ |
| Temperature of the inflowing cooling water | $T_{\text {Jacket,in }}$ | $[\mathrm{K}]$ |
| Specific heat transfer coefficient for the outer wall of the jacket chamber | $U A_{3}$ | $\left[\frac{\mathrm{~W}}{\mathrm{~K}}\right]$ |

Since the power input by the stirrer is unclear, the heat sources in the reactor cannot be calculated completely. However, comparative measurements can be carried out, if the stirrer speed is the same in both experiments. Similar to the impact of the stirrer, it is not necessary to bear the heat loss to the surrounding environment ( $\dot{Q}_{\text {Loss } 1}$ and $\dot{Q}_{\text {Loss 2 }}$ ) for the comparison in mind, since it occurs during the chemical and the electrical heat release in the same way. However, for studies about the absolute value of UA, this has to be regarded.

Furthermore, the inflow of $\mathrm{H}_{2} \mathrm{O}_{2}$ and outflow of medium, respectively, is only given in the continuous mode. Therefore, these influences have to be included. Their combined heat flow is described by

$$
\begin{equation*}
\dot{Q}_{\text {in-and outflow }}=\dot{m}_{\mathrm{H}_{2} \mathrm{O}_{2}} \cdot c_{p, \mathrm{H}_{2} \mathrm{O}_{2}} \cdot T_{\text {Environment }}-\dot{m}_{\text {Medium }} \cdot c_{p, \text { Medium }} \cdot T_{\text {Reactor }} \tag{80}
\end{equation*}
$$

Overall heat flow from the $\mathrm{H}_{2} \mathrm{O}_{2}$ inflow and the medium outflow $\dot{Q}_{\text {in-and outflow }} \quad[W]$ Volume flow rate of the $\mathrm{H}_{2} \mathrm{O}_{2}$ inflow and the medium outflow $\quad \dot{V}_{i, o} \quad\left[\frac{L}{S}\right]$
and

$$
\begin{equation*}
\dot{Q}_{\text {in-and outflow }}=\frac{\dot{V}_{i, o} \cdot\left(\rho_{\mathrm{H}_{2} \mathrm{O}_{2}} \cdot c_{p, \mathrm{H}_{2} \mathrm{O}_{2}} \cdot T_{\text {Environment }}-\rho_{\text {Medium }} \cdot c_{p, \text { Medium }} \cdot T_{\text {Reactor }}\right)}{\text { Density of } \mathrm{H}_{2} \mathrm{O}_{2} \quad \rho_{\mathrm{H}_{2} \mathrm{O}_{2}}} \tag{81}
\end{equation*}
$$

respectively.

In addition, the heat sink by the evaporated oxygen has to be taken into account. For its calculation the mass flow of oxygen is needed, which is given by

$$
\begin{equation*}
\dot{m}_{O_{2}}=\dot{V}_{i} \cdot c\left(H_{2} O_{2}\right)_{i} \cdot M_{O_{2}} \cdot \frac{1}{2} \cdot X \tag{82}
\end{equation*}
$$

| Volume flow rate of the $\mathrm{H}_{2} \mathrm{O}_{2}$ inflow | $\dot{V}_{i}$ | $\left[\frac{L}{s}\right]$ |
| :--- | :--- | :--- |
| Molarity of $\mathrm{O}_{2}$ | $M_{\mathrm{O}_{2}}$ | $\left[\frac{g}{m o l e}\right]$ |

As a result of this, it is possible to measure different heat flows from the reactor to the jacket for various power inputs. Since $\dot{Q}_{\text {loss }, 2}$ is insignificant as explained before, the balance equation for the jacket is given by

$$
\begin{equation*}
\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot T_{\text {Jacket,out }}=U A \cdot\left(T_{R}-T_{\text {Jacket,out }}\right)+\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot T_{\text {Jacket,in }} \tag{83}
\end{equation*}
$$

and can be transformed to

$$
\begin{equation*}
\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot\left(T_{\text {Jacket,out }}-T_{\text {Jacket,in }}\right)=U A \cdot\left(T_{R}-T_{\text {Jacket,out }}\right) \tag{84}
\end{equation*}
$$

and furthermore, to

$$
\begin{equation*}
\frac{\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot\left(T_{\text {Jacket,out }}-T_{\text {Jacket,in }}\right)}{\left(T_{R}-T_{\text {Jacket,out }}\right)}=U A \tag{85}
\end{equation*}
$$

The experimental data showed for higher specific power inputs a decrease of the in- and outlet temperature and, furthermore, an increase of their difference (Figure 47 and Figure 48). This trend was the same for the chemical and the electrical approach.

For the later, two different calibration heaters were studied ( 250 W and 500 W ) for precision reasons. With a high performance alternating voltage regulator the power input was set to the required set points.

Based on this data, UA was calculated for both methods at different specific power inputs. The profile showed a constant UA in the range of $18.2-24.2 \frac{w}{K}$ (250 W calibration heater) and $19.5-23.0 \frac{W}{K}$ ( 500 W calibration heater). The results, obtained with the chemical approach, fitted very well to the electrical ones. Despite of the measurement point at $32.4 \frac{\mathrm{~W}}{\mathrm{~L}}$, a specific heat transfer coefficient between 19.1-24.2 $\frac{W}{K}$ was determined. These fluctuations of all measurements and especially of the outlier from the mean value might be explainable by the influence of the environmental temperature. Since no insulation was used, a cooling effect (in case of outlet temperatures above the environmental temperature (Figure 47) and, respectively, a heating effect (during experiments with very low cooling water temperatures (Figure 48) occurred. In addition, the changing room temperature might have a further impact.

Figure 47: Temperature profile due to chemical heat production ( $\mathrm{P}_{\text {spec. }}=32.4 \frac{\mathrm{~W}}{\mathrm{~L}}$ ).

Figure 48: Temperature profile due to chemical heat production ( $\mathrm{P}_{\text {spec. }}=67.9 \frac{\mathrm{~W}}{\mathrm{~L}}$ ).

By a nonlinear least square minimisation the influence of the environment was analysed and $\dot{Q}_{\text {loss } 2}$ was taken into account. Then, the differential equation concerning the heat flows for steady state conditions are given by:

$$
\begin{gather*}
\dot{m}_{H_{2} O} \cdot c_{p, H_{2} O} \cdot\left(T_{\text {Jacket,out }}-T_{\text {Jacket, in }}\right)-U A \cdot\left(T_{R}-T_{\text {Jacket,out }}\right)  \tag{86}\\
+U A_{\text {loss } 2} \cdot\left(T_{\text {Environment }}-T_{\text {Jacket }, \text { out }}\right)=0
\end{gather*}
$$

The calculated results are presented in Figure 49. UA loss 2 was quite constant in a range of $1.98-2.04 \frac{W}{K}$ for all measurements, independent of the used heat source. Besides, the specific heat transfer coefficient from the reactor and the double jacket to the environment accounted only $8 \%$ of UA. Considering of $U A_{\text {loss } 2}$ changed the profile of UA and the outlier at $32.4 \frac{\mathrm{~W}}{\mathrm{~L}}$ only slightly. Apart from this deviation of $34.6 \frac{\mathrm{~W}}{\mathrm{~K}}$, UA was still in the range of $17.1-24.8 \frac{W}{K}$ for both methods.

Figure 49: Illustration of $U A$ and $U A_{\text {loss }}$ for different specific power inputs.

The main expected diverging factor on the findings is the feeding velocity. Lower feeding rates led to a more unsteady flow. In addition, the feeding tube was set above the surface
of the medium. Hence, a very thin tube, which is placed in a zone of high mixing, is suggested for upcoming experiments to enable a steadier flow and ideal mixing. Since the Watson Marlow 205U pump offers, compared to the Watson Marlow 520 pump, a more regular flow, due to the higher amount of pressure rollers, the utilisation of the first might be favourable.

All in all, additional examinations have to be made to find out the causing influence for the described deviation. Measurements should be made as well with specific power inputs less than $32 \frac{W}{L}$ to screen the UA profile for possible further high specific heat transfer coefficients, due to the described above coherence.

However, the newly developed method is suitable for the determination of UA in the range of about $50-70 \frac{W}{L}$ and lead to comparative results like the outcomes of the electrical approach by calibration heaters.

### 5.4.2 Determination of $\mathbf{k}_{\mathrm{L}} \mathbf{a}$

The presented new method was not only tested for its potential regarding the determination of the heat transfer but as well for its feasibility concerning studies on the mass transfer. At first the coalescence behaviour of the utilised medium was analysed. Dissolved compounds (especially salts) have a strong impact on the formed gas bubbles in aerated liquids. With increasing amounts of salts, a coalescence inhibition is observable (Marrucci and Nicodemo, 1967). Hence, media, which are applied for biological processes, can be assumed as non-coalescent due to their containing nutrients and salts. Liepe et al. mentioned, that a medium with an ion strength $<0.1 \frac{g}{m o l e}$ has to be expected as coalescent, whereas a liquid with an ion strength $>0.3 \frac{g}{m o l e}$ can be assumed as coalescence-inhibited (Liepe et al., 1998). For the newly developed $\mathrm{H}_{2} \mathrm{O}_{2}$ method 1x PBS-buffer was chosen, due to the recommendation of the literature (Meusel et al., unpublished). The utilised buffer has an ion strength of $0.2 \frac{g}{m o l e}$ and is therefore in the transitional range. To proof non-coalescent conditions and therefore, similar circumstances compared with biological media, different concentrations were tested on their $k_{L}$ a by means of the gassing-out method (Figure 50) (Meusel et al., unpublished). The outcomes showed an average $\mathrm{k}_{\mathrm{L}}$ of $287 \frac{1}{h}$ in the range of the $0.8-3.8$-fold of the
normal PBS-buffer-concentration. Higher dilutions led (after a transient zone) to a decreased $\mathrm{k}_{\mathrm{L}}$ a of about $133 \frac{1}{h}$.

Figure 50: Dependency of the $\mathrm{k}_{\mathrm{L}}$ a on the PBS-buffer concentration. Experimental setting: $500 \mathrm{rpm}, 1 \mathrm{vvm}$ air, $30^{\circ} \mathrm{C}$, 6-blade disk-impeller (diameter of 75 mm ), baffles, 3.5 L medium.

This phenomenon is explicable by the occurring coalescence in more diluted solutions, which involves bigger gas bubbles, a smaller total bubble surface and hence a decreased $\mathrm{k}_{\mathrm{L}}$. In contrast to that, for a 1 x PBS-buffer a coalescence-inhibited medium is present, which results in smaller air bubbles with a bigger overall surface and a higher $\mathrm{k}_{\mathrm{L}} \mathrm{a}$. In the sector of non-coalescent the specific boundary layer surface is independent from the exact salt concentration (Marrucci and Nicodemo, 1967). Hence, the slightly occurring dilution by the addition of the $\mathrm{H}_{2} \mathrm{O}_{2}$-solution and the formation of water by the reaction does not change the $\mathrm{k}_{\mathrm{L}}$ a.

The experimental settings were based on Hickmans $\mathrm{k}_{\mathrm{L}}$ a determination (Hickman, 1988). Because a flooding of the stirrer is possible at these configurations, a lower gassing rate was adjusted for the $\mathrm{k}_{\mathrm{L}}$ determination with the hydrogen peroxide method at different dilution rates (Figure 51). Furthermore, nitrogen instead of air was utilised to decrease the stationary dissolved oxygen concentration and hence, increase the measurable range.

With increasing flow rates, the obtained $\mathrm{k}_{\mathrm{L}}$ a got higher until it almost reached a constant value of $431 \mathrm{~h}^{-1}$. The obtained behaviour might be, similar to the inaccurate UA determination at low dilution rates (5.4.1), caused by an irregular flow. Further studies to investigate its stability with a higher mass flow were not possible. Due to the limitations of the digital control unit (DCU), the computer was not able to deal with higher currents than about 170 nA . A possible solution of this problem could be a current divider, to diminish the registered current.

Figure 51: Measured $\mathrm{k}_{\mathrm{L}}$ for different dilution rates. The measurement point at $0.04 \mathrm{~h}^{-1}$ (red) might be incorrect, due to the measurement limitations of the DCU. Experimental setting: $500 \mathrm{rpm}, 0.3 \mathrm{vvm}$ nitrogen, $30^{\circ} \mathrm{C}$, 6 -blade disk-impeller (diameter of 75 mm ), baffles, 3.5 L medium.

Due to this limitation, the measurement point with the highest dilution rate ( $38 \cdot 10^{-3} \mathrm{~h}^{-1}$ ) has already to been seen as critically and too high, because the recorded value was in a zone directly next to the registration border. It has to be taken into account, that the current varied in this area about 20 nA from the mean measurement, wherefore a distance of minimum 30 nA is needed for a distinct result (Figure 52).

Figure 52: Illustration of the current for different dilution rates.

The obtained results showed a higher $\mathrm{k}_{\mathrm{L}}$ a compared with the outcomes made before with the gassing-out method (264-287 $\mathrm{h}^{-1}$ ). Since this technique is a dynamic determination, a lower mass transfer is expected, due to the response time of the dissolved oxygen probe. Additionally, the driving force decreases over time, which influences the measurement as well (Garcia-Ochoa and Gomez, 2009). However, the lower gassing rate in the $\mathrm{H}_{2} \mathrm{O}_{2}$ experiments has to be considered (Table 9).

Hickmann found a constant kLa of $162-173 \mathrm{~h}^{-1}$ in his experiments (Hickman, 1988). He investigated the dilution rate range of $1.2 \cdot 10^{-3}-9.4 \cdot 10^{-3} \mathrm{~h}^{-1}$, where the measured $\mathrm{k}_{\mathrm{L}}$ in this thesis was $194-242 \mathrm{~h}^{-1}$. His experimental setting was very similar to the installation presented in this work. However, he used water instead of a salt solution like PBS. Hence, he worked in a coalescent medium, which leads to a decreased mass transfer. A contrary effect was introduced by a higher adjusted gas flow rate. Finally, other process affecting parameters, like the medium temperature, were not mentioned. These reasons explain his lower $\mathrm{k}_{\mathrm{L}} \mathrm{a}$.

The formation of oxygen takes place in the medium, wherefrom it diffuses to gas bubbles. Therefore, unlike the sodium thiosulfate method (3.2.3), where the oxygen is already consumed in the boundary layer (which increases the $\mathrm{k}_{\mathrm{L}}$ ), the Hatta number has not to
be considered for this approach. The Hatta number describes the ratio of the reaction rate to the mass transfer (equation (86)) (Hertwig and Martens, 2011; Liepe et al., 1998).

$$
\begin{array}{lll}
H a=\frac{\sqrt{k \cdot D_{c}}}{k_{L}} & \text { (for first order reactions) }  \tag{87}\\
\hline \text { Hatta number } & H a & {[-]} \\
\text { Diffusion coefficient } & D_{c} & {\left[\frac{m^{2}}{s}\right]}
\end{array}
$$

However, the causes for the unstable kla are still unclear, especially because Hickman reported a steady $\mathrm{k}_{\mathrm{L}}$ a in the studied dilution rate range. Therefore, the $\mathrm{H}_{2} \mathrm{O}_{2}$ method is still in the development phase and not ready to apply. Subsequent experiments are recommended in view of these obscurities. Furthermore, to enhance the comparability of this method with more results from the literature, it would be helpful to adjust the process conditions to settings occurring in fermentations ( $37{ }^{\circ} \mathrm{C}$, $1500 \mathrm{rpm}, 4.5 \mathrm{~L}$, 1.1 vvm , Air)

Table 9: Comparison of the experimental settings and the obtained $\mathrm{k}_{\mathrm{L}}$ a with different methods.

| $\mathrm{H}_{2} \mathrm{O}_{2}$-method <br> (own results) | $\mathrm{H}_{2} \mathrm{O}_{2}$-method <br> (Hickman, 1988) | Gassing-out method <br> (own results) |  |
| :---: | :---: | :---: | :---: |
|  | $30^{\circ} \mathrm{C}$ | Not mentioned | $30^{\circ} \mathrm{C}$ |
| Gassing rate | 0.3 vvm | 1.1 vvm | 1 vvm |
| Gas | $\mathrm{N}_{2}$ | Air | Air |
| Volume | 3.5 L | 5 L | 3.5 L |
| Medium | PBS-buffer | Water | PBS-buffer |
| Agitation | 500 rpm | 500 rpm | 500 rpm |
| $\mathrm{k}_{\mathrm{La}}$ | $431 \frac{1}{h}$ | $162-173 \frac{1}{h}$ | $264-287 \frac{1}{h}$ |

The exact Henry constant has a strong impact on the calculated $\mathrm{k}_{\mathrm{L}} \mathrm{a}$ and depends on various parameters (e.g. the salinity, the temperature and the pressure). Thus, it should be determined preliminary to further experiments. Since it is known for pure water, an easy procedure would be to calculate $\mathrm{H}_{\mathrm{PBS}, \mathrm{MnO}_{2}}{ }^{\mathrm{cc}}$ by comparative measurements with a Clark electrode for pure water and PBS medium with $\mathrm{MnO}_{2}$. Subsequently, the Henry constant is calculable by

| $\begin{equation*} H_{P B S, M n O_{2}}{ }^{c c}=\frac{c_{l, P B S, M n O_{2}}{ }^{*} \cdot H_{\text {Water }^{c}}{ }^{c c}}{c_{l, \text { Water }^{*}}} \tag{88} \end{equation*}$ |  |  |
| :---: | :---: | :---: |
| Henry constant for $\mathrm{PBS} / \mathrm{MnO}_{2}$ medium (dimensionless) | $\mathrm{PBBS}, \mathrm{MnO}_{2}{ }^{\text {cc }}$ | [-] |
| Oxygen saturation concentration of $\mathrm{PBS} / \mathrm{MnO}_{2}$ medium |  | $\left[\frac{\text { mole }}{L}\right]$ |
| Henry constant for pure water (dimensionless) | $H_{\text {Water }}{ }^{c c}$ | [-] |
| Oxygen saturation concentration of pure water | $c_{l, \text { Water }}{ }^{*}$ | $\left[\frac{\text { mole }}{L}\right]$ |

## Chapter 6

## Conclusion and Outlook

Knowledge about the heat and mass transfer in bioreactors is fundamental for a sufficient process regulation in both, microbial fermentation and cell culture cultivation. Present attempts are limited due to their dynamic measurement principle. Furthermore, in case of the heat transfer, they are restricted towards larger scales and uncommon geometries such as various single-use bioreactors. In this thesis, a new method is developed, which overcomes this limitations. This approach is based on the degradation of hydrogen peroxide, which is on the one hand a possible source of heat by its reaction enthalpy of $-98.2 \frac{\mathrm{~kJ}}{\text { mole }}$ and offers on the other hand the formation of oxygen. In a continuous process the stationary heat and oxygen production makes the measurement of the specific heat transfer coefficient and volumetric mass transfer coefficient comparatively more accurate than in dynamic attempts. In contrast to an electrical power input, this chemical heat production approach is independent of the design and scale of the bioreactor.

In order to develop such a continuous process, three different catalysts (catalase, $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ and $\mathrm{MnO}_{2}$ ) were studied concerning their kinetic, possible inactivation and safety issues. Based on these results, manganese oxide was chosen to be the most suitable candidate.
Subsequently, experiments in continuous mode were executed, but at first no steady state was achieved. It was shown, that this was due to the long term washing out effect and an inactivation. Therefore, a feeding strategy with an excess of $\mathrm{MnO}_{2}$ and, related to that, with a constant turnover of almost $100 \%$ was developed ( $6 \frac{g}{L}$ initially $+3 \frac{g}{L}$ every 60 minutes). The process was successfully scaled-up from 100 mL to the UniVessel ${ }^{\circledR}$ (5 L). In this scale, the newly established chemical method was compared with another one, based on an electrical power input by two calibration heaters to show its usability. The results showed the comparability of both methods, due to similar UA determinations in the range of $17.1-24.8 \frac{W}{K}$ at power inputs of about $50-70 \frac{W}{L}$.
However, at a specific power input of $32.4 \frac{\mathrm{~W}}{\mathrm{~L}}$ the chemical method obtained a higher UA of $34.6 \frac{\mathrm{~W}}{\mathrm{~K}}$. To investigate this specific section, more measurement points in this span should be analysed. Further research will deal with the determination of UA by this
chemical approach in single-use-bioreactors, especially in the wave-mixed BIOSTAT® ${ }^{\circledR}$ RM due to its uncommon geometry. In addition, it seems to be promising to process a further scale-up to volumes of 50 L in a stirred bioreactor to proof its capability for larger scales.

The investigations regarding the volumetric mass transfer coefficient showed that the determination of $\mathrm{k}_{\mathrm{L}}$ is not feasible yet. Stable results could not be measured. However, steady results are expected with dilution rates higher than $0.04 \mathrm{~h}^{-1}$. Hence, further studies are necessary to overcome these problems. Subsequent experiments with settings similar to fermentation conditions (regarding agitation, gassing rate, etc.) are advisable for better comparability to other approaches like the exhaust gas analysis. Finally, an exact determination of the Henry constant in the studied medium was suggested and described to overcome an imprecise calculation of the $\mathrm{k}_{\mathrm{L}}$.

## Appendix

Table 10: Chemicals and enzymes

| Chemicals | Manufacturer |
| :---: | :---: |
| Starch | Roth, Art. nr.: 9441.1 |
| $\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{3}$ | Roth, Art. nr.: HN 25.4 |
| KI | Roth, Art. nr.: 8491.2 |
| $\mathrm{H}_{2} \mathrm{O}_{2}(30 \%)$ | Roth, Art. nr.: CP26.1 |
| $\mathrm{HCl}(32 \%)$ | Roth, Art. nr.: P074.1 |
| $\mathrm{MnO}_{2}$ | Roth, Art. nr.: 7751.1 |
| $\mathrm{HNO}_{3}$ | Roth, Art. nr.: 4989.3 |
| $\mathrm{Fe}\left(\mathrm{NO}_{3}\right)_{3}$ | Roth, Art. nr.: CN84.1 |
| NaOH | Roth, Art. nr.: K021.1 |
| NaCl | Roth, Art. nr.: 3957.2 |
| KCl | Roth, Art. nr.: 6781.1 |
| $\mathrm{Na}_{2} \mathrm{HPO}_{4}$ | Roth, Art. nr.: P030.3 |
| $\mathrm{KH}_{2} \mathrm{PO}_{4}$ | Roth, Art. nr.: 3904.3 |
| EDTA- $\mathrm{Na}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ | Sigma-Aldrich, Art. nr.: 03685 |
| Catalase | Sigma-Aldrich, Art. nr.: C40 |

Table 11: Devices

| Devices | Article number, Manufacturer |
| :---: | :---: |
| Graduated burette ( 25 mL ) | Hirschmann |
| Graduated flasks (0.5, 1 and 2 L ) | Isolab Germany |
|  | CPA 10001, Sartorius |
| Balances | LA6 20S, Sartorius |
|  | GENIUS ME215S, Sartorius |
| Magnetic stirrer | IKA, RCT basic |
| Beaker ( 250 mL ) | Schott Duran |
| Escape | Bense Laborbau |
| Camera | Canon EOS 600D |
| Camera lens | Canon EF-S 18-55mm f/3.5-5.6 IS II |
| Temperature measurement device | Testo 435-2 |
| Pumps | 205 U, Watson Marlow |
|  | 520, Watson Marlow |
| Bioreactors | UniVessel ${ }^{\circledR}$ (2 L) (multi-use), Sartorius |
|  | UniVessel ${ }^{\circledR}$ (5 L) (multi-use), Sartorius |
| Cooling unit | Frigomix 1000, Sartorius |
| Digital control unit | Biostat B plus, Sartorius |
| Vacuum pump | 16692, Sartorius |
| Single-use Büchner funnel | Sartolab 180C6 (0.22 $\mu \mathrm{m}$ PES), Sartorius |
| Multi-use Büchner funnel | Not labelled, Sartorius |
| Scanning electron microscopically | FEI Quanta 200F |
| Sputter coater | Emitech K550 |
| Mass flow meter | 10 DX 3312 A, Fischer Porter |
| Filtration capsule | Sartopore $2(0.45+0.2 \mu \mathrm{~m})$, Sartorius |
| Tube sealer | BioSealer, Sartorius |
| Tubes ( 50 mL ) | Sarstedt |
| Insulation | Armaflex, Armacell |
| p02-probe | OxyFerm FDA 225, Hamilton |
| Exhaust-gas-analyser | Biopat Xgas, Sartorius |

Table 12: Calculation and normalisation of the reaction rate (part 1).
