I. SUMMARY

Serum response factor (SRF) regulates transcription of genes involved in a broad range of functional processes, ranging from cellular proliferation to muscle differentiation programs. The temporal and spatial fine tuning of SRF activity is achieved via its cooperation with a number of regulatory factors, most prominently, the ternary complex factors family and the myocardin-related transcription factors family (MRTFs). The latter includes proteins MRTF-A and MRTF-B, which are regulated by the changes in the monomeric actin dynamics in the cell. The repertoire of MRTF target genes ranges from cytoskeleton-associated proteins and muscle-specific genes to the components of signaling pathways, transcription factors and genes involved in cellular motility. Novel MRTF-controlled genes are still being actively discovered and validated.

In this work I first explored the regulation of two pro-apoptotic genes, Bok and Noxa, by the SRF-MRTF pathway and using chromatin immunoprecipitation and quantitative real-time PCR have shown that Bok is a direct target of the pathway, while Noxa is likely to be regulated by MRTFs, although not via serum response elements in the proximal promoter.

Second, employing the combination of apoptosis detection assays, I investigated the anti-proliferative effects of the constitutively active MRTF-A in fibroblasts and conclude that MRTF-A-induced cell death can be explained at least in part by the activation of apoptosis.

Third, I have shown that in fibroblasts MRTFs are required for normal cell proliferation and cell cycle progression. Their siRNA-mediated depletion leads to the down-regulation of CIP/KIP family members and premature entry into the S phase coupled with slightly extended G2 phase, as established by quantification of live cell imaging of cell cycle stages. Additionally, I observed an increased formation of nuclear defects during mitosis, which ultimately leads to aneuploidisation.

Finally, I have performed a mass-spectrometry screen for the G-actin-interacting proteins that display differential binding to the actin before and after stimulation with serum. Results of this screen can be used to explore the potential competitors with MRTFs for binding to G-actin upon extracellular stimuli.

The results of this work demonstrate that MRTFs have an important role in the regulation of cell proliferation, since both constitutively increased MRTF activity and its absence, result in the impairment of growth, albeit to a different extent. Moreover, this study for the first time establishes the connection between MRTFs and the regulation of cell cycle progression.

ZUSAMMENFASSUNG

Der "Serum Response Factor" (SRF) reguliert die Transkription von Genen, die, angefangen bei Zellproliferation bis hin zu Muskeldifferenzierungsprogrammen, in vielen verschiedenen funktionellen Prozessen involviert sind. Die zeitliche und örtliche Feinregulation der Aktivität von SRF wird durch sein Zusammenspiel mit zahlreichen Faktoren erreicht, vor allem mit der "ternary complex factors" Familie und der Familie der Myocardin-ähnlichen Transkriptionsfaktoren. Letztere beinhaltet MRTF-A und MRTF-B, die durch Änderungen in der Dynamik von monomerem Aktin in der Zelle reguliert werden. Das Repertoire an SRF-MRTF regulierten Genen reicht von Zytoskelett-assoziierten und muskelspezifischen Genen bis zu Komponenten von Signaltransduktionswegen und Genen, die für Zellmotilität verantwortlich sind.

In dieser Arbeit habe ich zuerst die SRF-MRTF –abhängige Regulation von zwei proapoptotischen Genen, Bok und Noxa, untersucht und konnte mittels Chromatinimmunopräzipitation und quantitativer Real-time PCR zeigen, dass Bok direkt durch SRF-MRTF reguliert wird, während Noxa wahrscheinlich durch MRTFs reguliert wird, aber nicht über die serum response elements im proximalen Promoter.

Zweitens habe ich mittels Tests zum Nachweis von Apoptose die antiproliferatorischen Effekte von konstitutiv aktivem MRTF-A in Fibroblasten analysiert und konnte nachweisen, dass MRTF-A induzierter Zelltod zumindest zum Teil durch die Aktivierung von Apoptose erklärt werden kann.

Drittens habe ich gezeigt, dass in Fibroblasten MRTFs für normale Zellproliferation und Ablauf des Zellzyklus benötigt werden. Deren siRNA vermittelte Depletion führt zu einer Herunterregulation von Mitgliedern der CIP/KIP Familie. Anhand Mikroskopie lebender, MRTF-depletierter Zellen und Quantifizierung derer Zellzyklusstadien konnte ein verfrühter Eintritt in die S-Phase, gekoppelt mit einer leicht verlängerten G2-Phase nachgewiesen werden. Des Weiteren habe ich in diesen Zellen vermehrte Kerndefekte während der Mitose beobachtet, was letztendlich zu Aneuploidie führt.

Zuletzt habe ich mittels Massenspektrometrie Proteinen identifiziert, die vor und nach Serumstimulation unterschiedliches Bindungsverhalten zu G-Aktin zeigen. Die Resultate dieses Screenings können verwendet werden, um mögliche Antagonisten von MRTFs bei der Bindung an G-Aktin nach extrazellulärer Stimulation zu finden.

Die Ergebnisse dieser Arbeit demonstrieren, dass MRTFs eine wichtige Rolle in der Regulation der Zellproliferation spielen, da sowohl konstitutiv erhöhte MRTF-Aktivität als auch Abwesenheit von MRTF zu Beeinträchtigung im Wachstum führt, wenn auch in unterschiedlichem Maß. Weiters konnte diese Arbeit zum ersten Mal eine Verbindung zwischen MRTFs und der Regulation des Zellzyklus herstellen.

II. INTRODUCTION

SRF

Back in 1984, the year I was born, Michael Greenberg and Edward Ziff from New York University Medical Center published a study describing an extremely rapid increase in *c-fos* proto-oncogene transcription in response to serum stimulation of quiescent BALB/c-3T3 A31 fibroblasts (Greenberg & Ziff, 1984). Two years later, Richard Treisman working at MRC LMB in Cambridge showed that this transient transcriptional activation requires a conserved DNA element 300 base pairs upstream from the mRNA cap site and a nuclear protein factor that specifically binds this element (Treisman, 1985; Deschamps *et al.*, 1985; Prywes and Roeder, 1986; Treisman, 1986). For convenience, he referred to the binding site as Serum Response Element (SRE) and to the binding protein as Serum Response Factor (SRF). Since then, SRF has become one of the best understood DNA-binding protein in the human proteome with more than 60 co-factors that modulate its activity identified to date (Miano, 2003).

In the years following SRF identification, the protein itself and its binding site were extensively characterized. The serum response element in the *c-fos* gene was originally identified as a 23-bp sequence containing symmetric inverted repeats flanking a 6-bp core (Treisman, 1986). An independent study (Minty & Kedes, 1986) identified a 10-bp element in the promoter of the cardiac α -actin gene which was highly conserved between human, mouse and chicken species. They called this element CCArGG box (CC(A-rich)GG), which was later found to be interchangeable with the serum response element in the *c-fos* gene

(Phan-Dihn-Tuy *et al.*, 1988; Boxer *et al.*, 1989; Taylor *et al.*, 1989). Nowadays, the SRF-binding site is termed CARG-box. Its consensus sequence is CC(A/T)₆GG, while single base deviations, usually C or G substitutions in the AT-core, result in non-consensus CARG-like elements, which can also be functional SRF-binding sites. SRF binds to the CARG boxes as a homodimer.

The murine SRF gene consists of 7 exons interrupted by 6 introns, spanning around 11 kilobases of the chromosome 17 (6p21 in human). Its cDNA has an open reading frame of 508 amino acids and four isoforms were identified differing in their 3' untranslated region (Norman *et al.*, 1988; Kemp & Metcalfe, 2000). The promoter of the SRF gene contains two evolutionary conserved SRF-binding sites (Spenser and Misra, 1996), suggesting that its expression might be regulated by a positive autoregulatory loop, in addition to Sp1-dependent transcription. The fact that SRF itself is induced by growth factors, such as serum and this induction is independent of *de novo* protein synthesis, makes it a member of so-called immediate early genes family (IEGs) (Norman *et al.*, 1988; Almedral *et al.*, 1988). SRF protein has been defined as a founding member of MADS-box family of transcriptional factors (Shore & Sharrocks, 1995). MADS box (MCM1, Agamous, Deficiens, SRF) is a modular 56 amino acid DNA-binding domain conserved in evolution from plants to mammals (Pellegrini *et al.*, 1995). In SRF, MADS box is located approximately in the middle of the polypeptide and is responsible for homodimerization, binding to DNA and interaction with other proteins (Shore & Sharrocks, 1995). The N-terminal part of SRF contains phosphorylation sites that can influence its DNA-binding and transcriptional potential (Misra *et al.*, 1991; Iyer *et al.*, 2003; Iyer *et al.*, 2006). The C-terminal region contains transcriptional activation domain (Johansen and Prywes, 1993), which does not belong to any standard class of activation domains (Tjan & Manniatis, 1994).

SRF is a ubiquitously expressed protein; its mRNA can be detected in most mouse tissues, while *in vitro*, SRF DNA binding was demonstrated in virtually all cell types. The deletion of SRF is incompatible with development. SRF-null mouse embryos fail to develop mesoderm and stop developing at gastrulation (Arsenian, 1998). Nevertheless, it appears that SRF is dispensable for cell proliferation *per se*, as evidenced by the normal growth of SRF-null mouse embryos until day E6.0 (Arsenian *et al.*, 1998), and seemingly normal proliferation rates of SRF-null mouse embryonic stem (ES) cells, although these cells lack serum-induced immediate-early gene (IEG) response and exhibit various defects in morphology and spreading (Schratt *et al.*, 2001). The precise role of SRF in the formation of mesoderm is not known, since SRF^{-/-} ES cells can be differentiated into mesoderm marker-expressing cells ex

vivo and form mesodermal cell types when introduced into nude mice (Weinhold *et al.*, 2000). Studies of conditional SRF deletion using cell type specific promoters as *Cre* recombinase drivers, established multiple roles of SRF in development and maintenance of many vital systems, including cardiovascular system (Parlakian *et al.*, 2004), skin development (Verdoni *et al.*, 2010), skeletal muscle (Li *et al.*, 2005; Charvet *et al.*, 2006), liver development (Sun *et al.*, 2009) and central nervous system (Alberti *et al.*, 2005). An excellent in-depth summary of SRF knockout phenotypes and their implication in pathological processes has been published recently (Miano, 2010).

Ever since SRF was found to regulate diverse and sometimes opposing sets of genes, ranging from genes controlling IEG response and cellular proliferation to cardiac or smooth muscle differentiation, it has become clear that the regulation of SRF-mediated transcription is complex and is mainly based on co-operation of SRF with accessory proteins and other transcriptional factors, which confer temporal and spatial specificity to gene expression. For example, homeodomain proteins, such as Phox1 were shown to physically interact with SRF to increase its DNA-binding activity *in vitro* (Grueneberg *et al.*, 1992). Angiotensin II was able to induce homeodomain protein MHox in a way that this induction resulted in the increase in SRF-dependent smooth muscle (SM) α -actin promoter activity (Hautmann *et al.*, 1997). Another homeodomain protein, *tinman* homolog Nkx-2.5, was recruited by SRF to cardiac α -actin promoter to potentiate the transcription (Chen and Schwartz, 1996). SRF and the GATA-4 co-activator were found to co-regulate myogenic and smooth muscle α -actin promoters as well as the *c-fos* promoter *in vitro* via protein-protein association (Belaguli *et al.*, 2000). Separate studies defined a complex of SRF and GATA-4 over the adjacent SRE and GATA-binding sites in cardiac *ANF* promoter (Morin *et al.*, 2001) and in developing chick embryos (Sepulveda *et al.*, 2002). Further studies in chick embryos identified LIM-domain only proteins CRP1 and CRP2 together with GATA-6, as modulators of the smooth muscle differentiation program in early development (Chang *et al.*, 2003). Finally, very recently, it was discovered that SRF and cell type specific transcriptional factors co-occupy regulatory DNA elements in the distal inter- or intragenic regions of chromatin, taking control of SRF-driven transcription away from the proximal promoters (Sullivan *et al.*, 2010; He *et al.*, 2011).

The studies mentioned above, however, were essentially overshadowed by the tremendous research effort aimed to characterize two families of transcriptional co-activators that appeared to play a major role in SRF regulation. These families are the Ternary Complex Factors (TCFs) and the myocardin family of transcription factors and I will discuss both of them below.

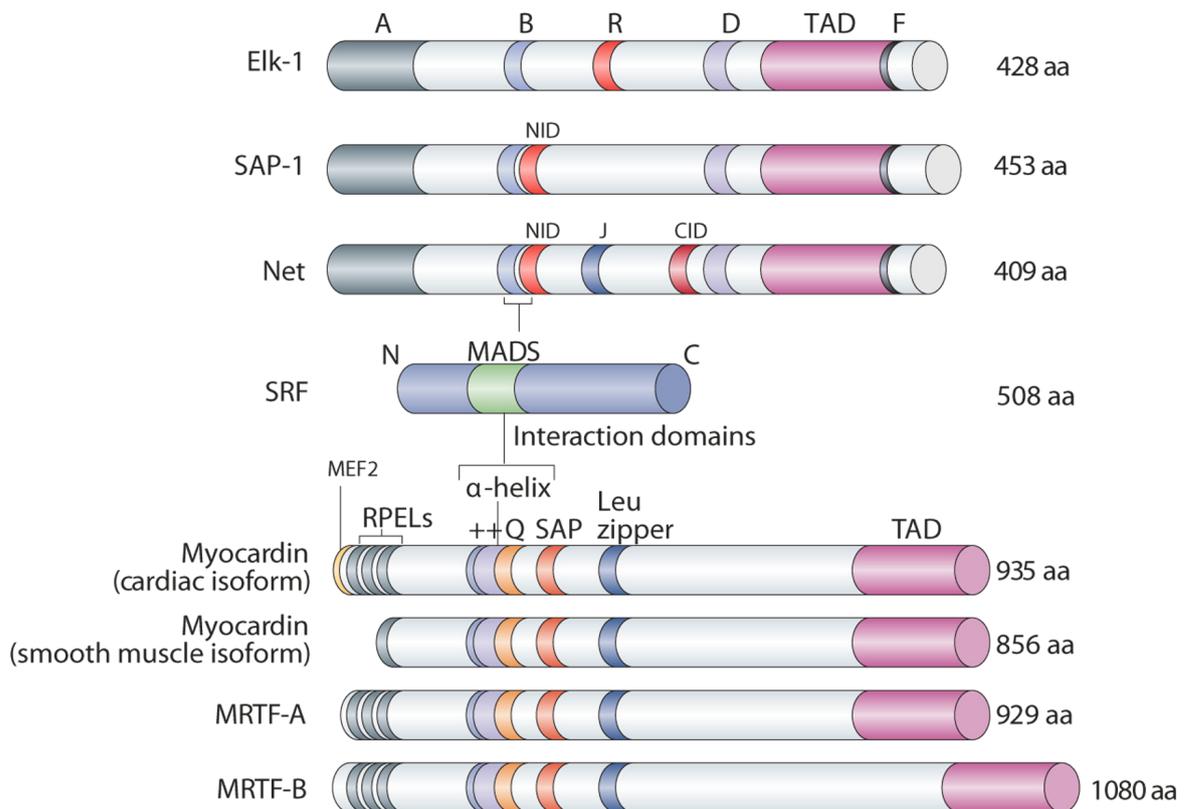

Figure II-1: Schematic representations of SRF and its co-activators. TCF family is shown on top. Conserved domains are represented as colored stripes. A-box is the Ets-DNA binding domain. B-box is the SRF-interaction domain. TAD is the transactivation domain responsible for transcriptional activity. It contains MAPK pathway phosphorylation sites. D-box and F-box are docking sites for MAP kinases. Net also contains additional docking site for JNK kinase (J box). R, NID and CID are repression domains. MRTF family is at the bottom. RPEL domains are G-actin-binding sites. ++ (B-box) and Q-box are responsible for interaction with SRF. SAP domain is a putative DNA-binding element. Leucine zipper is necessary for dimerization. TAD - transactivation domain. Cardiac form of myocardin contains MEF2-binding site at the N-terminus. *Modified from Olson & Nordheim, 2010 and Buchwalter et. al, 2004*

TCFs (Elk1, SAP-1, Net)

Historically, the first ternary complex factor was identified as a fraction of HeLa nuclear lysate that forms a ternary complex with SRF on the *c-fos* promoter (Shaw *et al.*, 1989). This novel protein was termed p62TCF, because of its 62 kDa molecular weight. Later it was shown to be what is now known as Elk-1 (Ets-like transcription factor 1) (Hipskind *et al.*, 1991). Two other related proteins, SAP-1 (SRF accessory protein 1), also known as Elk-4, and Net (Erp/Sap-2/Elk-3) were also identified shortly thereafter (Dalton & Treisman, 1992; Giovane *et al.*, 1994). All three proteins comprise a sub-family of one of the largest family of transcription factors – Ets family, which contains approximately 30 members. All Ets fam-

ily members, including TCFs retain a highly conserved 85 amino acid DNA-binding motif, called Ets domain (Wasylyk *et al.*, 1998). It recognizes a core sequence GGA(A/T), referred to as EBS (Ets-binding sequence). EBS motifs located in the vicinity of CArG boxes are necessary for ternary complex formation between TCFs and SRF, although TCFs can weakly bind EBS-SRE even in the absence of SRF (Janknecht *et al.*, 1993). Promoters of immediate early genes, (*c-fos*, *egr-1*, *egr-2*, *junB*, *pip92*, *Srf*) are constitutively occupied by SRF, while TCFs are recruited to it in a stimulus-dependent manner. Formation of the ternary complex unmasks transactivation domain of SRF, allowing full activation of transcription (Johansen and Prywes, 1993). Ternary complex factors confer an immense versatility and specificity to the SRF-mediated transcription due to the following facts:

- Many different upstream pathways activate TCFs. The most prominent activation signaling pathway is the MAPK cascade. In the absence of MAPK activity in NIH 3T3 cells, Net is a powerful repressor of transcription (Giovane *et al.*, 1994), Elk-1 activates transcription to some extent, and SAP-1 is inactive (Giovane *et al.*, 1994; Maira *et al.*, 1996). Following extracellular stimuli, which rely on one of the three major MAP kinases (ERK, JNK and p38), Elk-1 is activated by all three of them (Janknecht *et al.*, 1994; Gille *et al.*, 1995), Net is phosphorylated by ERK and p38 through its D-box, and by JNK through so-called J-box (Ducret *et al.*, 2000) and SAP-1 is efficiently targeted only by ERK and p38 (Strahl *et al.*, 1996). In addition to MAPK pathway, SAP-1 was shown to be activated by colony stimulating factor-1 (CSF-1) in macrophages (Hipskind *et al.*, 1994). FGF signaling also leads to Elk-1 phosphorylation by kinases other than ERK1/2 (Chung *et al.*, 1998).
- TCFs are tightly regulated via post-translational modifications. While for SAP-1, only activating phosphorylation has been reported (Strahl *et al.*, 1996), Elk-1 is antagonistically regulated via SUMO (Small Ubiquitin-related Modifier) modification which repressed Elk-1-directed transcriptional activity (possibly through altered nucleo-cytoplasmic shuttling), and phosphorylation via MAPK pathway, which potentiates transcription (Yang *et al.*, 2003; Salinas *et al.*, 2004). Net exhibits an even more complex pattern of regulation. In the absence of modifications it is a potent transcriptional repressor, while SUMOylation increases the repressive potential further (Wasylyk *et al.*, 2005). ERK and p38 can bind the D-box of Net, inducing phosphorylation of its transactivation domain, thereby converting Net from a repressor to an activator of transcription (Giovane *et al.*, 1994; Ducret *et al.*, 2000). JNK, on the other hand, binds the J-box in the middle of the protein, which induces phosphorylation of the adjacent export motif. This

phosphorylation leads to the export of Net from the nucleus into the cytoplasm, leading to release from the transcriptional repression (Ducret *et al.*, 1999).

- TCFs cooperate with additional factors besides SRF to modulate gene expression. One of the best known examples are p53-mediated inhibition of Net phosphorylation (Nakade *et al.*, 2004), and co-operation between transcriptional factors HIF-1 α and HIF-2 α with Elk-1 and Net to regulate transcription under hypoxic conditions (Yan *et al.*, 1999; Serchov *et al.*, 2010; Gross *et al.*, 2007; Gross *et al.*, 2008).

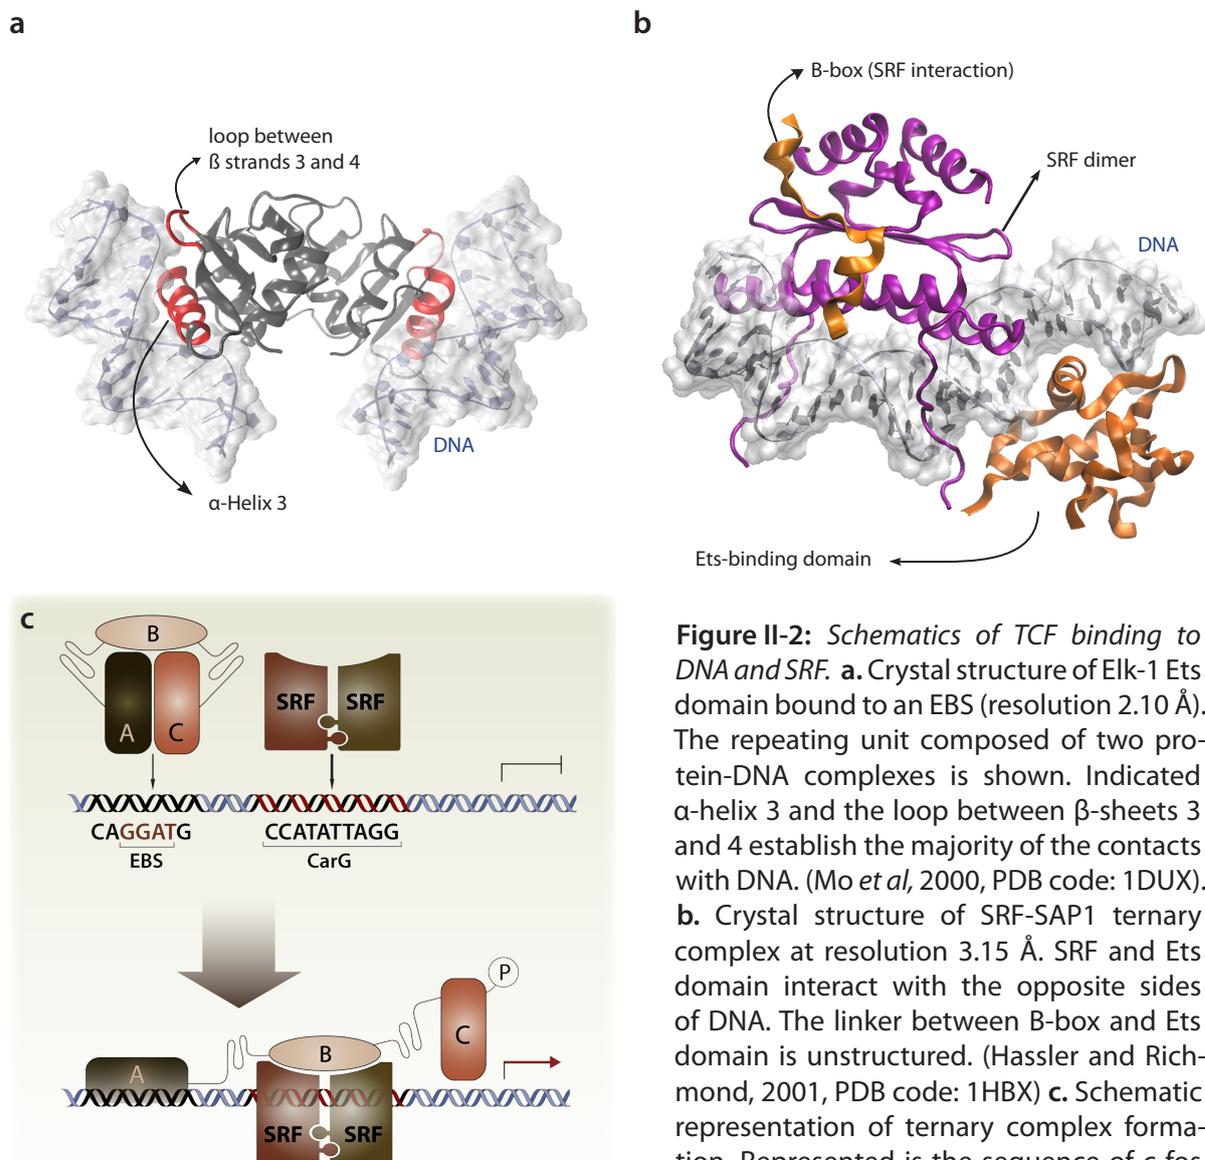

Figure II-2: Schematics of TCF binding to DNA and SRF. **a.** Crystal structure of Elk-1 Ets domain bound to an EBS (resolution 2.10 Å). The repeating unit composed of two protein-DNA complexes is shown. Indicated α -helix 3 and the loop between β -sheets 3 and 4 establish the majority of the contacts with DNA. (Mo *et al.*, 2000, PDB code: 1DUX). **b.** Crystal structure of SRF-SAP1 ternary complex at resolution 3.15 Å. SRF and Ets domain interact with the opposite sides of DNA. The linker between B-box and Ets domain is unstructured. (Hassler and Richmond, 2001, PDB code: 1HBX) **c.** Schematic representation of ternary complex formation. Represented is the sequence of c-fos EBS and CARG box. SRF dimer interacts with

CarG box. A-box of TCFs binds EBS. B-box contains the interface for interaction with SRF. Trans-activation C-domain controls the transcription activity of the complex.

Despite the large number of studies on the regulation of ternary complex factors, their role *in vivo* remains incompletely understood. Studies using homologous recombination in mice are apparently hindered by the fact that there is a high degree of redundancy between TCFs. Net mutant mice seem to have a specific defect in the thoracic lymphatic vessels, which manifests in accumulation of chyle in lungs and death from respiratory failure (Ayadi *et al.*, 2001). Also, Net seems to be required for normal angiogenesis in adult (Zheng *et al.*, 2003). Phenotypes of Elk-1 and SAP-1 deficient mice display very few abnormalities. Further studies using combinational knockouts are necessary for delineating the roles of TCFs in embryonic development and maintenance of the adult organism.

Myocardin family

The myocardin family of transcription factors is the second most studied family of the SRF activity modulators. In mammals there are three members in the family – myocardin (MYOCD), MRTF-A (MAL/BSAC/Mkl1) and MRTF-B (Mkl2/MAL16). Structurally, they share homology in several functional domains and have been classified into the SAP family of proteins. The SAP domain comprises 35 amino acid helix-linker-helix stretch, named after SAF-A/B, Acinus and PIAS proteins. This domain has DNA-binding properties and was implicated in chromosomal dynamics, nuclear breakdown and apoptotic DNA fragmentation (Aravind & Koonin, 2000). The role of the SAP domain in MRTFs has not been clearly established, although it is known that its deletion abolishes the ability of myocardin to activate cardiac-specific *ANF* gene *in vitro* (Wang *et al.*, 2001). Functions of most of the other structural domains in MRTFs have been elucidated. N-terminal part is occupied by the RPEL motifs containing RPxxxEL core sequence which bind G-actin (Posern *et al.*, 2002; Miralles *et al.*, 2003). C-terminally from the RPEL motifs there is a B-box and glutamine-rich Q domain, which are required for interaction with SRF. A leucine-zipper motif necessary for dimerization is approximately in the middle of the polypeptide and the C-terminal part harbors a transactivation domain which mediates transcriptional activity. Due to important differences between the founding member myocardin and MRTF-A/B, I will discuss these proteins separately, although they do display some degree of redundancy.

Myocardin

Myocardin was first identified in an *in silico* screen for genes expressed exclusively in the heart (Wang *et al.*, 2001) and since then has emerged as one of the most important regulators

of cardiac and smooth muscle differentiation programs (Wang *et al.*, 2001; Wang *et al.*, 2002; Wang *et al.*, 2003; Du *et al.*, 2003; Li *et al.*, 2003; Yoshida *et al.*, 2003; Chen *et al.*, 2002). During embryogenesis, its expression is first detected in cardiac precursor cells at ca. E7.5 and thereafter maintained in cardiac myocytes and smooth muscle cell lineages throughout adulthood (Wang *et al.*, 2001; Du *et al.*, 2003). Two alternatively spliced isoforms of myocardin have been identified – a longer, 935 amino acid form, has been primarily detected in the mouse heart, while a shorter, 856 aa form is expressed predominantly in smooth muscle cells (Creemers *et al.*, 2006b). The N-terminus of myocardin contains two RPEL motifs, but they have diverged from the consensus sequence to the point where myocardin does not bind G-actin and localizes exclusively in the nucleus (Miralles *et al.*, 2003). Myocardin binds SRF as a dimer (Wang *et al.*, 2003) and activates transcription of many cardiac and smooth muscle-restricted genes, including SM22 α , smooth muscle myosin heavy chain (SM-MHC), SM myosin light chain (SM-MLC), SM- α -actin, cardiac α -actin and smoothelin-A. It is currently not known if any CARG-flanking DNA sequences are necessary for the myocardin binding. Myocardin is perhaps the only known smooth muscle-specific gene (also *HRCBP* (Anderson *et al.*, 2004)) that does not have SRF-responsive elements in the immediate promoter, although *in vitro* it does respond to SRF-mediated stimuli. Its expression has been explored in detail during mouse embryogenesis and

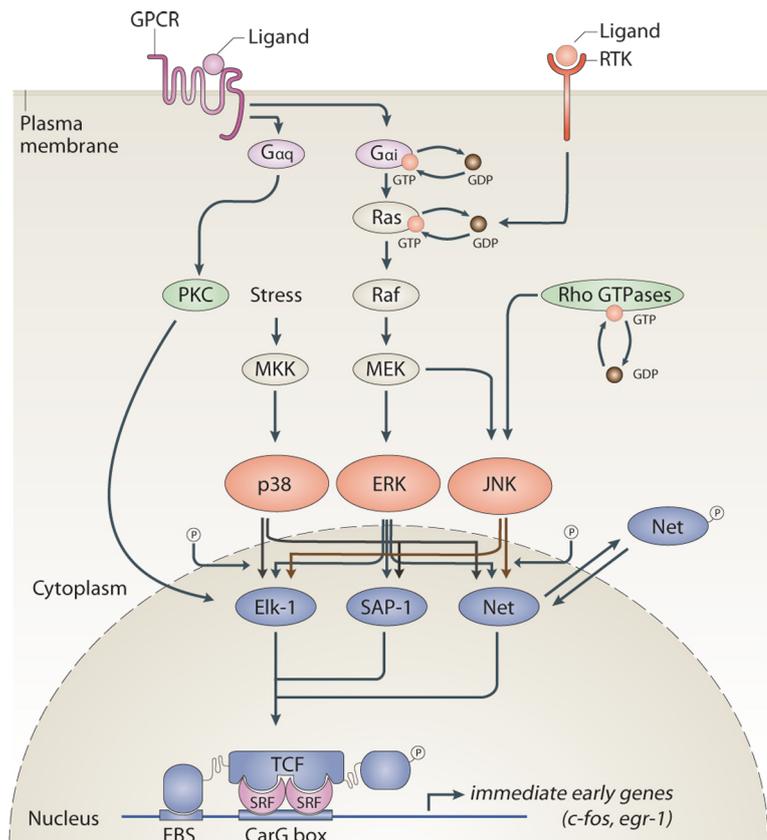

Figure II-3: Pathways leading to the activation of ternary complex factors. Only main TCFs (Elk-1, SAP-1 and Net) are shown. Extracellular stimuli that promote the activity of heterotrimeric G-protein (α i and α q subunits) and small GTPase Ras, activate downstream signaling pathways that result in phosphorylation of TCFs through their transactivation domain. The most prominent activation pathway is Raf-MEK-ERK. Elk-1 can be phosphorylated by p38, ERK and JNK, while SAP-1 is only efficiently activated by ERK and p38. Net is phosphorylated by ERK and p38 through D-box and by JNK through J-box. The latter phosphorylation leads to nuclear export of Net and suppression of transcription. Represented pathways could be cell type specific.

turned out to be rather unique. An enhancer 20-30 kb upstream of the myocardin gene has been shown to be a direct target of the transcriptional factors MEF2, Tead and Foxo, which drive its expression in early cardiac lineage during embryogenesis. Interestingly, the longer cardiac form of myocardin was found to interact and activate Mef2, which in turn activates transcription of myocardin itself in a positive autoregulatory loop. The shorter smooth muscle specific isoform does not have a Mef2 interaction site (Creemers *et al.*, 2006a). Also, this regulation appears to be SRF-independent.

Precise molecular mechanisms that govern myocardin-driven heart and smooth muscle programs are still poorly understood. Ectopical expression of myocardin in fibroblasts and ES cells triggers expression of smooth muscle, rather than cardiac genes (Yoshida *et al.*, 2003; Du *et al.*, 2003), while injecting myocardin mRNA into *Xenopus* embryos results in activation of cardiac genes (Small *et al.*, 2005). Myocardin-*null* mouse embryos survive only until day E10.5 due to block of vascular smooth muscle differentiation, especially in the aorta; the hearts of the embryos until then appear to be normal (Li *et al.*, 2003). To some extent this rather mild cardiac phenotype of myocardin-*null* mice could be explained by redundancy with MRTF-A/B which might be expressed in the early developing heart. In *Xenopus*, where MRTFs are not expressed at such early stages of development, expression of dominant negative version of myocardin led to the complete elimination of heart differentiation (Wang *et al.*, 2001), while morpholino-directed knockdown of myocardin resulted in disruptions in heart tube formation but generally had much milder phenotype (Small *et al.*, 2005).

Smooth muscle cells can modulate their phenotype in response to various external stimuli, such as injury. As a result, quiescent cells expressing high levels of contractile proteins switch to a proliferating type, expressing high levels of growth factors and extracellular matrix (Owens *et al.*, 2004). This phenomenon was explored in great detail to identify the mechanism used by SRF to differentiate between growth-promoting and muscle-restricted transcription. Apparently, many, but not all smooth muscle genes contain TCF binding sites in the vicinity of CARG boxes. It has been shown that in smooth muscle cells myocardin and TCFs associate with SRF in a mutually exclusive manner. External stimuli, for example PDGF, stimulate Elk-1 phosphorylation. Active Elk-1 is able to actively replace myocardin on the promoters of smooth muscle genes, which leads to the repression of their transcription. At the same time, direct TCF targets from IEG group of genes ensure that the cell starts proliferating (Miralles *et al.*, 2003; Wang *et al.*, 2004). Consistently with this, lowering endogenous

levels of Elk-1 in smooth muscle cells leads to an increase in expression of myocardin targets (Zhou *et al.*, 2005). Smooth muscle cells can also transdifferentiate with skeletal muscle (Odelberg *et al.*, 2000). It has been convincingly shown that myocardin play a crucial role in the conversion of skeletal muscle into smooth muscle via a complex chain of event, requiring inhibition of myogenin promoter via silencing by HDAC5 and physical contact of myocardin with MyoD transcriptional factor, which blocks DNA binding ability of MyoD and transcriptional synergy with MEF2, thereby inactivating all three master regulators of skeletal muscle differentiation (Long *et al.*, 2007).

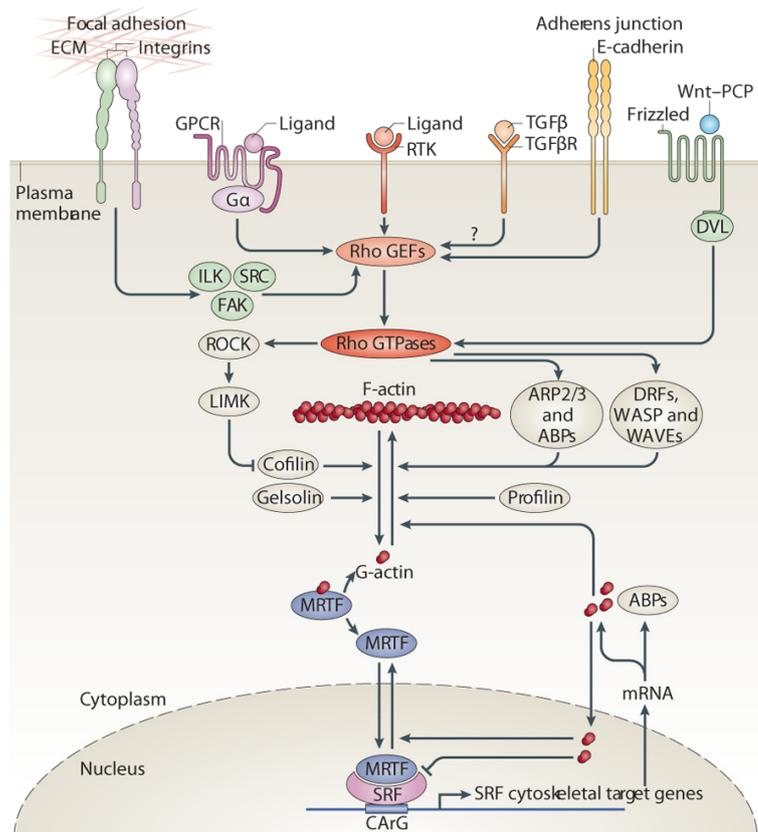

Figure II-4: Pathways leading to the activation of MRTF-A/B. Cytoskeletal actin filament dynamic is affected by a number of membrane receptors, including protein tyrosine kinases, G protein-coupled receptors (GPCR) with $G\alpha_{12/13}$ subunits, E-cadherins, integrins and other. Small GTPases from Rho family play a central role in regulating signals to G-actin-mediated activation and inactivation of MRTF-A/B. High levels of G-actin retain MRTF-A/B in the cytoplasm. Incorporation of G-actin into F-actin filaments depletes pool of free G-actin, allowing MRTF-A/B to escape from repressive complex, enter the nucleus and activate SRF-driven transcription of a MRTF-dependent subclass of SRF target genes. From Olson and Nordheim, 2010

In addition, myocardin activity is known to be regulated by a number of additional factors, such as GATA-4 (Oh *et al.*, 2004), homeodomain protein Nkx3.1 (Sun *et al.*, 2009), Tbx5 (Wang *et al.*, 2011) and Smad3 (CArG-box independently) (Qui *et al.*, 2005). Since some of this cooperation partners have previously been reported for SRF itself, it would be important to determine if they represent real third layer of regulation above SRF-MYOCD, or some of these studies are interchangeable.

Recent studies have embarked on potentially novel mechanisms which can regulate myocardin activity, adding more complexity to the SRF-controlled network. Work from Chen *et al.*, 2001 has shown that myocardin can induce expression of micro-RNA-1 in smooth

muscle cells, which leads to inhibition of their proliferation. Similarly to Elk1, myocardin was found to be SUMOylated, but unlike Elk1, SUMO-1 modification enhanced myocardin's activity (Wang *et al.*, 2007). Another study discovered that acetylation is also required for myocardin to activate its target genes (Cao *et al.*, 2012).

MRTF-A/B

Early research on SRF cooperation with ternary complex factors has shown that inactivating TCFs does not fully abolish serum-induced activation of c-fos promoter, suggesting that at least two independent pathways activate SRF: TCF-dependent and TCF-independent (Johansen & Prywes, 1994; Hill *et al.*, 1994 and references therein). This TCF-independent pathway was shown to be responsive to the effectors of heterotrimeric G proteins lysophosphatidic acid (LPA) and aluminium fluoride ion (AlF₄⁻) and required small GTPases from the Rho family: RhoA, Rac and Cdc42 (Hill *et al.*, 1995a; Hill and Treisman, 1995b). Many details linking Rho signaling to the activation of SRF have emerged thereafter, finally leading to the realization that cytoskeletal actin dynamics is closely involved in this process (Sotiropoulos *et al.*, 1999). In mouse fibroblasts, RhoA activity coupled to the activation of Diaphanous-related formin-1 (mDia1) and downstream changes in actin treadmilling were necessary for activation of SRF-dependent transcription, while the activities of downstream RhoA targets ROCK kinase and LIM kinase were not required (Sahai *et al.*, 1998; Sotiropoulos *et al.*, 1999; Tominaga *et al.*, 2000; Copeland *et al.*, 2002). In contrast, in the aortic smooth muscle cells ROCK kinase activity was indispensable (Mack *et al.*, 2001) and in the neuronal cell line PC12 the presence of ROCK, LIMK and mDia1 (Geneste *et al.*, 2002). Actin mutants which cannot be polymerized were shown to have inhibitory effect on SRF-mediated transcription, while mutants which were stabilized in the polymerized form, activated SRF reporters (Posern *et al.*, 2002). Nevertheless, despite extensive research efforts unraveling upstream pathways leading to TCF-independent SRF activation, the SRF-interacting cofactor mediating this response was not known.

In 2001, two independent publications appeared describing the genetic defect behind a rare condition affecting infants and young children – acute megacaryoblastic leukemia (AMKL). Chromosomal translocation t(1;22)(p13;q13) associated exclusively with AMKL was found to result in a fusion protein, consisting of a fragment of unknown SAP domain-containing MKL1 polypeptide and RNA-binding motif protein 15 (RBM15, alternatively

OTT (from one-twenty-two)). Because it was involved in megakaryocytic acute leukemia, the MKL1 protein was named MAL. (Ma *et al.*, 2001; Mercher *et al.*, 2001). Almost two years later, in 2002, MAL was described again as a myocardin-related transcriptional factor A (MRTF-A), together with closely related MRTF-B. Both of them were found to be potent co-activators of SRF-mediated transcription and required SRF for their activity (Wang *et al.*, 2002). Another independent study has identified a mouse MRTF-A isoform, named BSAC, during the screen

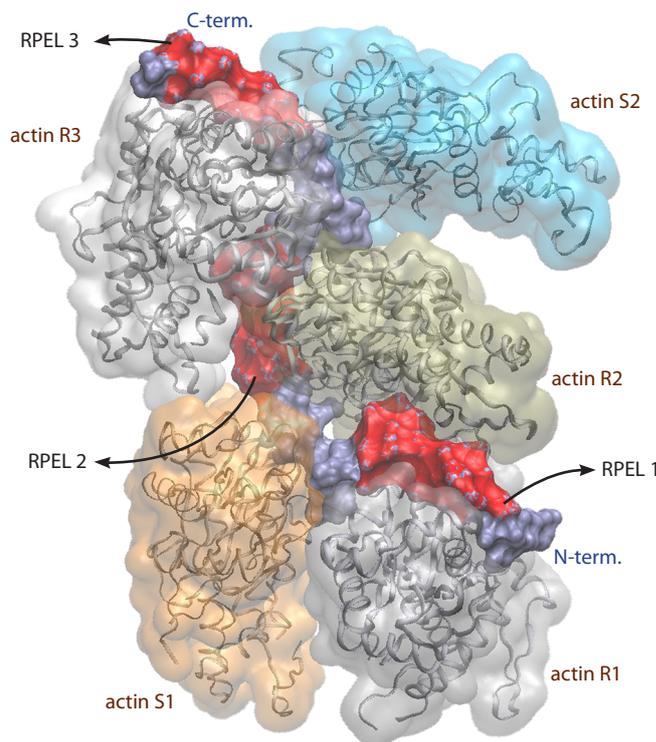

Figure II-5: Crystal structure of MRTF-A RPEL domains bound to 5 G-actin molecules. Complex of RPEL domains of MRTF-A (residues 67 to 199) with G-actin, ATP and latrunculin B was resolved at 3.5 Å resolution. Each RPEL motif engages a G-actin, designated here as actins R1-R2-R3. Helical N-terminal extensions of RPEL2 and RPEL3 recruit two other actins to the spacer elements - actins S1 and S2. RPEL-3 has considerably weaker affinity to actin, actins R3 and S2 can easily dissociate from MRTF-A, forming a trimeric complex. Residues involved in the interactions are mostly conserved between MRTF-A and MRTF-B. The cytoplasmic localisation of MRTF-A in unstimulated cells requires the integrity of both spacer sequences and binding of actin to spacer sequences is required for MRTF-A nuclear export. Modified from Mouilleiron *et al.*, 2011. PDB code: 2YJF

for anti-apoptotic proteins (Sasazuki *et al.*, 2002). Shortly thereafter MRTF-A/B were defined as Rho-regulated SRF co-activators, connecting small GTPases from Rho family with the actin cytoskeleton and SRF-driven transcription.

MRTF-A/B unlike myocardin, are ubiquitously expressed in a broad range of cell types, including cardiac and smooth muscle cells. In non-stimulated NIH 3T3 cells MRTF-A/B are sequestered in the cytoplasm via interaction of their N-terminal RPEL motifs with monomeric G-actin (Miralles *et al.*, 2003, Posern *et al.*, 2004). Rho-mediated signaling (from LPA or serum) stimulates F-actin polymerization in the cytoplasm, depleting the G-actin pool and releasing MRTF-A/B from the inhibitory complex. Following importin α/β -mediated import, they bind SRF as a dimer and activate transcription of target genes (Miralles *et al.*, 2003; Posern *et al.*, 2004; Pawlowski *et al.*, 2010; Hirano *et al.*, 2011). It is not known if any of the

CAR_G-box flanking sequences are necessary for the binding, although MRTF-DNA contact has been reported and is necessary for efficient complex formation (Zaromytidou *et al.*, 2006). Nuclear G-actin also forms complexes with MRTF-A/B, facilitating its Crm1-dependent export into the cytoplasm and thus inhibiting transcriptional activity (Vartiainen *et al.*, 2007). Since the β -actin gene is one of the MRTF-SRF targets, ongoing rise in G-actin levels ensures downregulation of SRF response and retention of MRTFs in the cytoplasm. This regulatory mechanism was mostly studied in mouse fibroblasts and muscle cells. In contrast, in primary neurons and breast cancer epithelial cells MRTF-A is constitutively nuclear, suggesting existence of additional regulatory mechanisms (Kalita *et al.*, 2006; Medjkane *et al.*, 2009).

MRTF-A/B bind the same surface on SRF as TCFs. Similarly to the myocardin and Elk1 competition, mutually exclusive binding of MRTF-A/B and TCFs has been postulated (Murai *et al.*, 2002; Zaromytidou *et al.*, 2006). Moreover, the ability of MRTF-A/B to heterodimerize with myocardin in muscle cells has been found to direct some transcriptional targets (Wang *et al.*, 2003). With respect to the co-activator families, SRF target genes were proposed to be divided into two types – MRTF-dependent actin-regulated genes (*vinculin*, *actin*, *Srf*, *Cyr61* etc.) and TCF-dependent MAPK-regulated genes (IEGs). This division was based on the studies of upstream stimuli on the SRF-driven transcription in NIH 3T3 cells (Gineitis and Treisman, 2001). However, how exactly this level of separation is achieved *in vivo* and what is the role of MRTF-TCF competition/redundancy still remains elusive.

Similarly to myocardin and TCFs, MRTF-A/B were found to be additionally regulated by interacting with other factors as well as by post-translational modifications. Stimulation of NIH 3T3 cells with serum or TPA (phorbol ester 12-O-tetradecanoyl-13-acetate) promotes not only nuclear translocation of MRTFs followed by transcriptional activation, but also Erk-dependent phosphorylation of MRTF-A on serine 454. This phosphorylation appears to act as an additional off-switch for MRTF-SRF activity, since it promotes binding of MRTFs to G-actin and nuclear export (Muehlich *et al.*, 2008). A number of other phosphorylation sites in MRTF-A/B were identified in a high-throughput mass spectrometry screen (Olsen *et al.*, 2006), but their functional importance has not been elucidated. SUMOylation has also been reported for MRTF-A. Like in Elk1, but unlike in myocardin, this modification correlated with decreased activation potential of MRTF-A (Nakagawa and Kuzumaki, 2005).

A few reports have established that MRTF-A/B might also act in an SRF-independent manner. During epithelial-mesenchymal transition of MDCK cells, MRTF-A/B were found to physically interact with Smad3 (previously seen for myocardin) upon exposure

to TGF- β , and direct transcription of another transcription factor – Slug, which, in turn directly repressed E-cadherin expression, leading to dissociation of cell contacts (Morita *et al.*, 2007). Intriguingly, dissociation of cell-cell contacts, in particular adherens junctions, is sufficient to activate MRTF-SRF pathway and transcription of target genes in the same MDCK cells (Busche *et al.*, 2008, Busche *et al.*, 2010). In C2C12 skeletal muscle cells, MRTF-A was found to be in complex with Smad 1/4. This complex was actively transcribing Id3 gene, whose product is a potent inhibitor of myogenic differentiation. Upon differentiation, one of the forkhead family transcription factors, Foxo1, translocated into the nucleus, forming inhibitory complex with MRTF-A/Smad 1/4 and suppressing Id3 transcription (Iwasaki *et al.*, 2008). Of note, this study opposing findings of others indicating that MRTF-A/B is necessary for skeletal muscle differentiation because MRTF-A knockdown in C2C12 cells blocks their ability to differentiate (Selvaraj and Prywes, 2003). Another study showed mechanical stress-induced, MRTF-A dependent transcription of extracellular matrix protein tenascin-C (Asparuhova *et al.*, 2011). Interestingly, this regulation appeared to be completely SRF-independent.

A protein named SCAI (suppressor of cancer cell invasion) has been described as a negative regulator of MRTF-A (Brandt *et al.*, 2009). It binds to the RPEL motifs/B-box of MRTF-A and myocardin and suppresses their transcriptional activity without affecting MRTF-SRF binding. Finally, the LIM-only protein Fhl2 which is a direct transcriptional target of SRF was shown to compete with MRTF-A for SRF binding on the promoters of smooth muscle, but not immediate early or cardiac genes (Phillipar *et al.*, 2004).

Single MRTF-A or MRTF-B knockout phenotypes do not phenocopy SRF knockout, consistent with the idea that there is a significant degree of redundancy between them. To date, two MRTF-A null phenotypes are described. One is viable and does not exhibit any obvious abnormalities, except that MRTF-A mutant females are unable to productively nurse their offspring due to a very specific defects in mammary myoepithelial cells, which are required for ejection of milk from the mammary gland during lactation (Li *et al.*, 2006). This defect manifests in severely attenuated genes coding for smooth muscle restricted contractile proteins, such as SM- α -actin, SM-MHC, calponin 1 and tropomyosin 2. These mice were also found to have defective hypertrophic responses to chronic pressure overload in heart, as determined by angiotensin-II treatment (Kuwahara *et al.*, 2010). Second MRTF-A null phenotype was essentially similar to the one described before in respect to mammary gland dysfunction. In addition to this, around 40% of MRTF-A null embryos suffered lethal cardiac cell

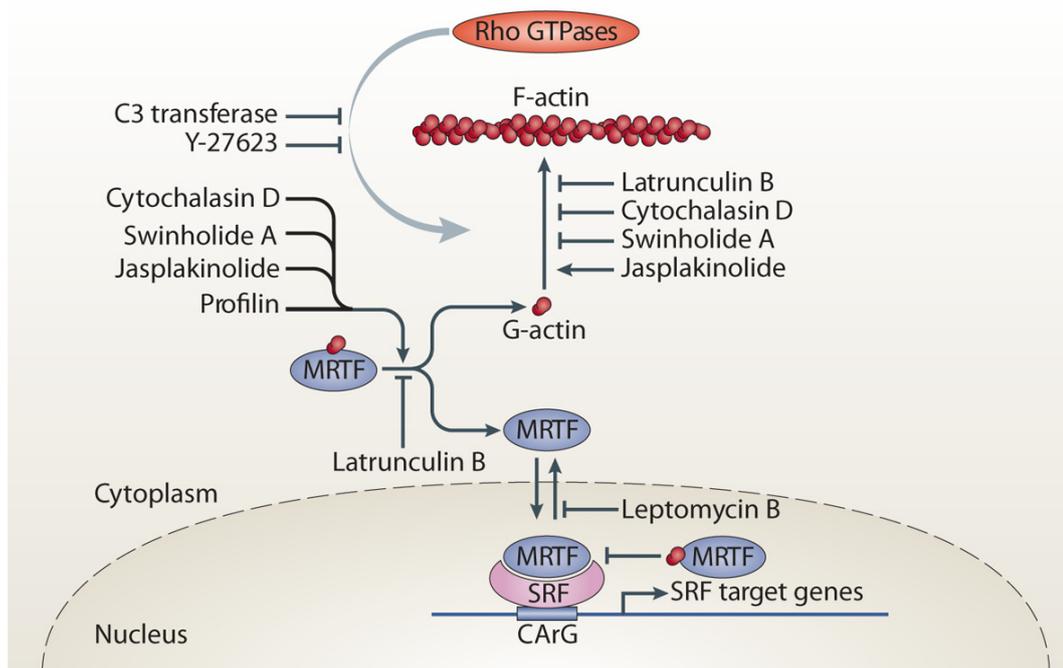

Figure II-6: *In vitro* modulators of MRTF-SRF pathway. For explanations see text. From Olson and Nordheim, 2010

necrosis at day E10.5 (Sun *et al.*, 2006b). Reasons for this discrepancy between phenotypes have not been established.

Global MRTF-B knockout was reported in three studies. Li *et al.*, 2005 used gene trap strategy to generate functionally null MRTF-B mutant protein. Homozygous embryos died between E17.5 and P1, exhibiting a spectrum of cardiac outflow tract defects (interrupted aortic arch, double-outlet right ventricle and others). Observed defects apparently stemmed from the cell autonomous flaw in differentiation of smooth muscle cells from the cardiac neural crest. Oh *et al.*, 2005 used gene targeting strategy to generate MRTF-B null phenotype. These mice died at E13.5-E14.5 with nearly identical spectrum of cardiac outflow tract defects. Wei *et al.*, 2007 generated yet another gene trap-targeted MRTF-B mutant with *null* phenotype. In addition to cardiac defects, hemorrhages in liver and dilations of vitelline veins that connect the embryo to the yolk sac, were observed. Targeted deletion of both MRTF-A and MRTF-B in the heart was also reported. While double cardiac knockout mice were born at Mendelian ratios, 75% of them died at P1, while the rest 25% gradually between weeks 2 and 13 (M. Mokalled, doctoral dissertation). Reported cardiac defects ranged from endocardial fibrosis and cardiac dilation to disarrangement of cardiomyocytes. Targeted deletion of both MRTF-A/B in megakaryocyte lineage has led to macrothrombocytopenia, platelet cytoskeletal abnormalities and severely impaired platelet activation (Smith *et al.*, 2012). Finally, conditional deletion of MRTF-A and -B in the brain results in lethality at

P16-P21. Mutant mice display morphological abnormalities in the hippocampus, cerebral cortex and subventricular zone (Mokkaleed *et al.*, 2010). Interestingly, a single copy of MRTF-A or –B is sufficient to support normal brain development, while the double knockout mimics the phenotype observed upon brain-specific SRF ablation (Knöll *et al.*, 2006).

SRF-MRTFs in proliferation and cell cycle regulation

The role of SRF in the G1-S phase transition of cultured cells, especially fibroblasts, via cooperation with ternary complex factors and induction of immediate early genes is very well established (see above). The yeast SRF homolog MCM1 is necessary for G2-M phase transition (Althoefer *et al.*, 1995). However, the multitude of *in vivo* and *in vitro* studies suggests that the effects of SRF and its co-activators on cell proliferation are very likely to be context and cell type-specific. Murine ES cells are able to proliferate at normal rates (Schratt *et al.*, 2001), however, differentiating ES cells *in vitro* and epiblasts *in vivo* require SRF-mediated anti-apoptotic Bcl-2 expression for survival (Schratt *et al.*, 2004; Niu *et al.*, 2005). Conditional SRF depletion in liver showed impaired regeneration of tissue after partial hepatectomy, associated with blunted IEG response. SRF, however, was not strictly required for the regeneration process, although in normal mice its levels were acutely upregulated in response to injury (Latasa *et al.*, 2007). In the neuronal system, constitutively active SRF has been shown to be beneficial for survival of motoneurons upon nerve fiber injury (Stern *et al.*, 2012) and SRF-deficient neurons displayed signs of neurodegeneration (Beck *et al.*, 2012). In contrast, Ramanan *et al.*, reported that SRF-deficient neurons did not show decrease in viability or defects in morphology (Ramanan *et al.*, 2005). Also, brain-specific SRF ablation led to severe impairments in neuronal migration, but did not affect survival (Alberti *et al.*, 2005).

Myocardin was shown to inhibit proliferation of cardiomyocytes and aortic smooth muscle cells at least in part via antagonizing NF- κ B-dependent cell proliferation (Tang *et al.*, 2008) and its knockdown using siRNA led to an increase in proliferation of fibroblasts (Milyavsky *et al.*, 2007). MRTF-A has been shown to confer anti-proliferative effects on fibroblasts, partly via induction of the negative regulator of EGFR signaling – Mig6 (Descot *et al.*, 2009). In contrast, MRTF-A was also shown to possess anti-apoptotic effects in Traf2/Traf5 double knockout mouse embryonic fibroblasts (Sasazuki *et al.*, 2002).

Practical methods to manipulate the SRF-MRTF pathway

Research in the field of SRF-MRTF-mediated transcription has been greatly facilitated by the use of agents that modulate MRTF function directly or change the state of actin equilibrium in a cell. The actin-targeting natural compounds cytochalasin D, jasplakinolide and swinholide A disrupt the MRTF-G-actin inhibitory complex, thereby liberating MRTFs and activating target gene transcription. Latrunculin B, on the other hand inhibits dissociation of MRTF-G-actin, preventing the activation of transcription (Miralles *et al*, 2003; Posern *et al*, 2004; Vartiainen *et al*, 2007). Three of these compounds, cytochalasin D, swinholide A and latrunculin B impair actin polymerization, while jasplakinolide stabilizes F-actin structures (Allingham *et al*, 2006). Effects of the upstream Rho-mediated signaling can be efficiently inhibited with either clostridial toxin C3 transferase (RhoA inhibitor), or with the ROCK-inhibiting agent Y-27623. Because nuclear MRTF-G-actin complexes also inhibit activation of SRF and stimulate MRTF export into the cytoplasm, ectopic expression of actin fused to a nuclear localization signal will have a strong inhibitory effect on MRTF-SRF transcription. Over-expression of actin mutants has also been useful in studying MRTF-dependent regulation of SRF. Non-polymerizable variants G13R and R62D can inhibit MRTF activity, while S14C and V159N stimulate F-actin formation and activate MRTF-driven transcription (Posern *et al*, 2002). MRTF variants lacking RPEL motifs and SRF-interacting domain (B1-box) ($\Delta N\Delta B$) or RPEL motifs and C-terminal transactivation domain ($\Delta N\Delta C$) act in a dominant-negative manner, suppressing activity of endogenous MRTFs.

III. MATERIALS AND METHODS

Materials

III.1.1. Equipment [selected items used in this study]

Agarose gel equipment	Horizontal Elpho	Workshop of MPI of Biochemistry (Martinsried)
Balances	Kern 572 and Kern ABS 120-4 Mettler AE200	Kern & Sohn GmbH (Balingen) Mettler Toledo (Giessen)
Centrifuges	Microcentrifuge 5417R Microcentrifuge 5417C Allegra 6KR Sorvall Evolution RC Universal 16	Eppendorf AG (Wesseling-Berzdorf) Beckman Coulter (Krefeld) Thermo Scientific (USA) Hettich (Kirchlengern)
PAGE equipment	Mini-PROTEAN 3 Elpho B100 XCell SureLock® Mini-Cell	Bio-Rad (Munich) Workshop of MPI of Biochemistry (Martinsried) Invitrogen (Darmstadt)
Western blotting	Mini Trans-Blot® electrophoretic transfer cell	Bio-Rad (Munich)
Power supplies	Consort/Peqlab EV261	distributed by Peqlab (Erlangen)
Microplate reader	Labsystems Multiscan RC model 351	Thermo Scientific (USA)
Luminometer	Microlummat Plus LB 96V Labsystems Fluoroscan Ascent FL type 374	EG&G Berthold (Schwerzenbach, CH) Thermo Scientific (USA)

Spectro-photometer	BioPhotometer™ Nanodrop, ND1000 and 2000c	Eppendorf AG (Wesseling-Berzdorf) Thermo Scientific (USA)
Electroporation	Genepulser XCell™	Bio-Rad (Munich)
Gel documentation	IDA gel documentation system LAS-1000 gel documentation system ChemiDoc™ XRS gel documentation system	Raytest (Straubenhardt) FujiFilm (Düsseldorf) Bio-rad (Munich)
PCR equipment	Thermocycler T3000 StepOnePlus™ real-time PCR system LightCycler® 480 II real-time PCR system	Biometra (Göttingen) Applied Biosystems (Darmstadt) Roche (Mannheim)
Microscopes	Axio Observer.A1 Axioplan 2 Axio Observer.Z1	Zeiss (Jena)
FACS machines	FACSCalibur flow cytometer FACSAria II cell sorter Accuri C6 flow cytometer	BD Biosciences (USA)
Mass spectrometry	LTQ-Orbitrap mass spectrometer Agilent 1100 nanoflow HPLC system	Thermo Scientific (USA) Agilent Technologies (USA)
Sonication	HD3100 sonicator	Bandelin (Berlin)
Incubation	HERAcell® 150i CO2 incubator XL S1 incubator equipped with TempModule S, CO2 module S and heating unit XL S	Thermo Scientific (USA) Pecon GmbH (Erbach)

III.1.2. Chemicals and Reagents

General laboratory chemicals

2-Mercaptoethanol.....	Merck (Darmstadt)
2-Propanol, absolute	Carl Roth GmbH (Carlsruhe)
Acetic acid, glacial, 100%.....	Merck (Darmstadt)
Acetonitrile	Sigma-Aldrich (Steinheim)
Acrylamide/Bis solution [37.5:1 (30% w/v), 2.6% C]	Serva (Heidelberg)
Agar-Agar, bacteriological grade.....	Carl Roth GmbH (Carlsruhe)
Agarose, for routine use.....	Sigma-Aldrich (Steinheim)
Albumin from bovine serum	Sigma-Aldrich (Steinheim)
Ammonium bicarbonate (NH ₄ HCO ₃).....	Sigma-Aldrich (Steinheim)
Ammonium persulfate (APS).....	Bio-Rad (Munich)
BES (N,N-Bis(2-hydroxyethyl)-2-aminoethanesulfonic acid)	Carl Roth GmbH (Carlsruhe)
Boric acid (H ₂ BO ₃)	Sigma-Aldrich (Steinheim)
Calcium chloride (CaCl ₂).....	Carl Roth GmbH (Carlsruhe)

Chelex® 100 ion exchange resin.....	Bio-Rad (Munich)
Chloroquine	Sigma-Aldrich (Steinheim)
Dimethyl sulfoxide (DMSO)	Sigma-Aldrich (Steinheim)
DL-Dithiothreitol, for molecular biology.....	Sigma-Aldrich (Steinheim)
Ethidium bromide, 1% solution	Carl Roth GmbH (Carlsruhe)
Ethyl alcohol, absolute	Sigma-Aldrich (Steinheim)
Ethylenediaminetetraacetic acid (EDTA).....	Carl Roth GmbH (Carlsruhe)
Formaldehyde, 16% solution	Pierce (Sankt Augustin)
Gelatin, from cold water fish skin, 45%	Sigma-Aldrich (Steinheim)
Glycerol, 87% for molecular biology	Merck (Darmstadt)
Glycine, molecular biology grade.....	Sigma-Aldrich (Steinheim)
HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid).....	Sigma-Aldrich (Steinheim)
Hydrochloric acid (HCl), 37%	Sigma-Aldrich (Steinheim)
Lithium chloride	Sigma-Aldrich (Steinheim)
Magnesium chloride (MgCl ₂).....	Carl Roth GmbH (Carlsruhe)
Methyl alcohol, absolute	Carl Roth GmbH (Carlsruhe)
Monopotassium phosphate (KH ₂ PO ₄).....	Sigma-Aldrich (Steinheim)
Moviol 4-88.....	Sigma-Aldrich (Steinheim)
Non-fat milk powder, blotting grade	Carl Roth GmbH (Carlsruhe)
Paraformaldehyde (PFA)	Sigma-Aldrich (Steinheim)
Polybrene (hexadimethrine bromide)	Sigma-Aldrich (Steinheim)
Ponceau-S [0.1% (w/v) solution in 5% acetic acid].....	Sigma-Aldrich (Steinheim)
Potassium chloride (KCl)	Sigma-Aldrich (Steinheim)
Propidium iodide.....	Sigma-Aldrich (Steinheim)
Sodium acetate (CH ₃ COONa)	Sigma-Aldrich (Steinheim)
Sodium bicarbonate (NaHCO ₃).....	Sigma-Aldrich (Steinheim)
Sodium chloride (NaCl)	Sigma-Aldrich (Steinheim)
Sodium hydroxide (NaOH).....	Calbiochem (Nottingham, UK)
Sodium phosphate dibasic (Na ₂ HPO ₄).....	Sigma-Aldrich (Steinheim)
TEMED (N,N,N',N'-Tetramethylethylenediamine)	Serva (Heidelberg)
Theazoyl blue tetrazolium bromide (MTT)	Sigma-Aldrich (Steinheim)
Trifluoroacetic acid (TFA)	Sigma-Aldrich (Steinheim)
Tris base (Trisma®)	Sigma-Aldrich (Steinheim)
Tryptone/Peptone.....	Carl Roth GmbH (Carlsruhe)
Yeast extract, bacteriological grade	Carl Roth GmbH (Carlsruhe)

Detergents

Nonidet® P-40 Substitute (NP-40).....	Fluka (Buchs, CH)
Sodium deoxycholate, powder	Sigma-Aldrich (Steinheim)
Sodium dodecyl sulfate (SDS), powder.....	Carl Roth GmbH (Carlsruhe)
Triton X-100	Serva (Heidelberg)
Tween 20	Sigma-Aldrich (Steinheim)

Antibiotics

Ampicillin	Roche (Mannheim)
Blasticidine S hydrochloride.....	Sigma-Aldrich (Steinheim)
G418 disulfate salt (<i>Geneticin</i>).....	PAA (Cölbe)
Kanamycin sulphate.....	Invitrogen (Karlsruhe)
Puromycin dichloride.....	Calbiochem (Nottingham,GB)
Zeocin™ [100 mg/ml solution].....	Invitrogen (Karlsruhe)

Composite reagents and kits

100 bp ladder.....	NEB (Frankfurt am Main)
2-log DNA ladder (0.1-10 kb)	NEB (Frankfurt am Main)
Annexin V-FITC apoptosis detection kit I.....	BD Biosciences (Heidelberg)
ANTI-FLAG® M2 magnetic beads.....	Sigma-Aldrich (Steinheim)
Colloidal Blue staining kit.....	Invitrogen (Karsruhe)
Complete™ protease inhibitor cocktail	Roche (Mannheim)
Dual-Glo™ Luciferase Assay Kit.....	Promega (Madison, USA)
Dynabeads® Protein G	Invitrogen (Karsruhe)
Fast SYBR® Green master mix.....	Applied Biosystems (Darmstadt)
FITC BrdU Flow Kit.....	BD Biosciences (Heidelberg)
Gel loading dye, blue (6X)	NEB (Frankfurt am Main)
Immobilon-P PVDF membrane	Millipore (Billerica, USA)
Micro BCA™ protein assay kit	Pierce (Sankt Augustin)
NuPAGE® LDS sample buffer (4X)	Invitrogen (Karsruhe)
PCR marker	NEB (Frankfurt am Main)
PE Caspase-3 active apoptosis kit I.....	BD Biosciences (Heidelberg)
PhoSTOP™ phosphatase inhibitor coctail	Roche (Mannheim)
Precision Plus Protein™ dual color standards.....	Bio-Rad (Munich)
QIAGEN Plasmid Maxi Kit.....	Qiagen (Hilden)
QIAGEN Plasmid Mini Kit	Qiagen (Hilden)
QIAGEN RNeasy Mini Kit	Qiagen (Hilden)
QIAquick Gel Extraction Kit.....	Qiagen (Hilden)
QIAquick MinElute Gel Extraction Kit.....	Qiagen (Hilden)
QIAquick MinElute PCR Purification Kit.....	Qiagen (Hilden)
QIAquick PCR Purification Kit.....	Qiagen (Hilden)
Restore™ Western blot stripping buffer	Pierce (Sankt Augustin)
Verso™ cDNA kit.....	Thermo Scientific (Schwerte)
Western Lightning®-ECL	PerkinElmer (Boston, USA)

Enzymes and reagents used in molecular cloning

All restriction endonucleases purchased from.....	NEB (Frankfurt am Main)
Alkaline phosphatase, calf intestinal (CIP).....	NEB (Frankfurt am Main)
Deoxynucleotide (dNTP) solution mix, 10 mM each	NEB (Frankfurt am Main)

DNA polymerase I, large (Klenow) fragment.....	NEB (Frankfurt am Main)
Phusion® high-fidelity DNA polymerase.....	Thermo Scientific (Schwerte)
Proteinase K, 20 mg/ml.....	NEB (Frankfurt am Main)
Ribonuclease A (RNAse A) from bovine pancreas	Sigma-Aldrich (Steinheim)
T4 DNA ligase.....	NEB (Frankfurt am Main)
Taq DNA polymerase.....	NEB (Frankfurt am Main)
Trypsin, sequencing grade.....	Promega (Madison, USA)

Transfection reagents

Lipofectamine™ reagent.....	Invitrogen (Karsruhe)
Lipofectamine™ 2000 reagent.....	Invitrogen (Karsruhe)
Lipofectamine™ RNAiMAX reagent.....	Invitrogen (Karsruhe)

Cell culture reagents

DMEM, high glucose, no Glu, no Lys, no Arg (Gibco®)	Invitrogen (Karsruhe)
DMEM, high glucose, without phenol red (Gibco®).....	Invitrogen (Karsruhe)
Dulbecco's modified Eagle medium (Gibco® DMEM), high glucose (4.5g/L).....	Invitrogen (Karsruhe)
Fetal bovine serum	Invitrogen (Karsruhe)
Fetal bovine serum, dialysed.....	Invitrogen (Karsruhe)
L-[U- ¹³ C ₆ , ¹⁴ N ₂]lysine (Lys8)	Sigma-Aldrich (Steinheim)
L-[U- ¹³ C ₆ , ¹⁵ N ₄]arginine (Arg10).....	Sigma-Aldrich (Steinheim)
L-arginine (Arg0).....	Sigma-Aldrich (Steinheim)
L-glutamine, 200 mM (100X).....	PAA (Cölbe)
L-lysine (Lys0).....	Sigma-Aldrich (Steinheim)
Opti-MEM® reduced serum medium (Gibco®)	Invitrogen (Karsruhe)
Penicillin-Streptomycin, liquid, 100X	PAA (Cölbe)
Sodium pyruvate, 100 mM (100X).....	PAA (Cölbe)
Trypsin-EDTA solution, 10X.....	PAA (Cölbe)

Inhibitors and inducers

Cycloheximide.....	Sigma-Aldrich (Steinheim)
Cytochalasin D.....	Calbiochem (Nottingham,GB)
Doxorubicine	Sigma-Aldrich (Steinheim)
Doxycyclin, Hyclate.....	Calbiochem (Nottingham,GB)
Etoposide	Calbiochem (Nottingham,GB)
Jasplakinolide	Calbiochem (Nottingham,GB)
Latrunculin B.....	Calbiochem (Nottingham,GB)
Staurosporine	Sigma-Aldrich (Steinheim)
TNF alpha	Sigma-Aldrich (Steinheim)
z-VAD-FMK.....	Biomol (Hamburg)

III.1.3. Common buffers and solutions

Most of single component solutions were made at 1M concentration. pH was adjusted when necessary. Following autoclaving, solutions were stored at room temperature. Exceptions are 3M KCl, 5M NaCl, 0.5M EDTA, 10% SDS, 10% Na-deoxycholate. Below are universally used buffers. For protocol-specific recipes, see Methods section.

TE buffer (1x)

Tris-HCl, pH 8.0	10 mM
EDTA	1 mM

TBS buffer (1x)

Tris-HCl, pH 7.5	20 mM
NaCl	150 mM

TBS/T buffer (1x)

Tris-HCl, pH 7.5	20 mM
NaCl	150 mM
Tween 20	0.1% (v/v)

BBS buffer (2x)

BES	50 mM
NaCl	280 mM
Na ₂ HPO ₄	1.5 mM
pH	6.96

PBS pH 7.4

KCl	2.7 mM
NaCl	137 mM
Na ₂ HPO ₄	10 mM
KH ₂ PO ₄	1.8 mM

TBE buffer (1x)

III.1.4. Antibodies and staining reagents

Primary reagents

Reagent	Description	Source	Used in
anti-FLAG M2 Peroxidase	Mouse monoclonal IgG ₁ conjugated to horseradish peroxidase (HRP)	Sigma-Aldrich cat. A8592	WB 1:2000
anti-MRTF-A/B	Rabbit polyclonal serum	Homemade (Sina Pleiner)	WB 1:1000 IF: 1:500 ChIP: 300 µl
anti-SRF	Rabbit polyclonal, clone G-20	Santa Cruz Biotechnology cat. sc-335	ChIP: 5 µg
anti-NF2	Rabbit polyclonal, clone A-19	Santa Cruz Biotechnology cat. sc-331	ChIP: 5 µg
anti-α-tubulin	Mouse monoclonal IgG ₁ , clone DM1A	Sigma-Aldrich cat. T9026	WB 1:10000
anti-p21Waf1	Mouse monoclonal IgG ₁ , clone 65	Calbiochem cat. OP76	WB 1:1000
anti-p27Kip1	Mouse monoclonal IgG ₁	BD Biosciences cat. 610242	WB 1:1000
anti-p53	Mouse monoclonal IgG ₁ , clone 1C12	Cell Signaling cat. 2524	WB 1:1000
anti-cyclin D1	Mouse monoclonal IgG ₁ , clone D1-72-13G-11	Millipore cat. 05-815	WB 1:1000
anti-Rb (total)	Rabbit polyclonal, clone C-15	Santa Cruz Biotechnology cat. sc-50	WB 1:100
anti-phospho-Rb (Ser ⁷⁸⁰)	Rabbit monoclonal IgG, clone C84F6	Cell Signaling cat. 3590	WB 1:1000
anti-GFP	Mouse monoclonal, clone GFP-20	Sigma-Aldrich cat. G6539	WB 1:2000
DAPI, Molecular Probes®	4',6-Diamidino-2-Phenylindole, Dihydrochloride	Invitrogen cat. D1306	IF 1:5000
Hoechst 33258	Pentahydrate (bis-Benzimide)	Invitrogen cat. H-3569	IF 1:5000
Phalloidin-Atto 488	Marker for F-actin	Sigma-Aldrich cat. 49409	IF 1:100

Secondary reagents

Reagent	Source	Used in
Alexa Fluor® 546 goat anti-rabbit	Molecular Probes (Eugene, USA)	IF 1:1000
Polyclonal goat anti-mouse-HRP	DakoCytomation (Glostrup, Denmark)	WB 1:5000
Polyclonal swine anti-rabbit-HRP	DakoCytomation (Glostrup, Denmark)	WB 1:2000

Phoenix E	Second generation retrovirus producer cell line, based on 293T cells (human embryonic kidney cells transformed with adenovirus E1a and carrying temperature-sensitive T antigen co-selected with neomycin)	Created by G.P.Nolan (Stanford, USA) Provided by A.Ullrich (MPI for Biochemistry, Martinsried)
NIH 3T3- shMAL	NIH 3T3 cells stably expressing shRNA against MRTF-A/B from pSUPER.retro.puro plasmid	This study
NIH 3T3 –pSUPER.retro.puro empty vector	NIH 3T3 cells with incorporated pSUPER.retro.puro vector. Used as negative control for NIH 3T3-shMAL cell line	This study

III.1.8. Culture media

Bacterial media

Lysogeny broth (LB) was used for propagation of bacterial cultures. It contained the following components per 1L: 10g Tryptone/peptone; 5g yeast extract; 10g NaCl. If necessary, supplemented with 100 µg/mL ampicillin, or 30 µg/mL kanamycin. Solid medium produced by adding 1.5% agar-agar.

Mammalian cell culture medium

All cell lines were routinely maintained in **full DMEM**: high glucose (4.5 g/L) + 1X L-glutamine,+ 1X sodium pyruvate,+ 1X penicillin-streptomycin + 10% FBS.

Freezing medium..... full DMEM with 20% FBS (instead of 10%) + 10% DMSO

Serum starvation medium full DMEM with 0.5% FBS or 0.2% BSA (instead of 10% FBS)

Live microscopy medium..... full DMEM (10% FBS) without phenol red.

SILAC labeling medium full DMEM (10% dialyzed FBS) without Arginine and Lysine, supplemented with Arg0 and Lys0 (light medium) or Arg10 and Lys8 (heavy medium).

Methods

III.2.1. Molecular cloning and DNA manipulation methods

Preparation of electrocompetent bacteria

Single colony of DH5 α cells, grown on LB-agar plate, was inoculated into 5 mL of LB broth and incubated overnight (37°C, 180 RPM) to generate starter culture. Starter culture was diluted 1:100 in fresh LB broth and grown until OD₆₀₀ = 0.5-0.6. Cells harvested by centrifugation (1200xg, 10 min, 4°C). Pellet was re-suspended in equal to the original volume of ice-cold 10% glycerol and incubated for 20 min at 4°C. Cells centrifuged as before and re-suspended in 10% of the original volume of ice-cold 10% glycerol followed by incubation for 20 min at 4°C. Cells were pelleted again and re-suspended in 2 ml of 10% glycerol, aliquoted in eppendorf tubes (40 μ L each) and shock-frozen in liquid nitrogen. Aliquots stored at -80°C. Every new preparation routinely tested for transformation efficiency by electroporating 1 ng of pUC18 plasmid. Batches with efficiencies less than 5x10⁷ colonies per μ g of DNA were discarded.

Electroporation of competent bacteria

40 μ L aliquots of electrocompetent bacteria were thawed on ice. DNA (ligation reactions – no more than 5 μ L, purified DNA – 5-15 ng) was added and mixture was transferred into an ice-cold electroporation cuvette (0.2 cm, Bio-Rad). Electroporated using Genepulser XCell™ with the following settings: 2.5 kV, 25 μ F and 200 Ohm. After zapping, 500 μ L of pre-warmed LB medium was added and cells were incubated at 37°C with shaking for 60 minutes. 20 and 200 μ L aliquots were plated onto LB-agar plates containing appropriate antibiotics and incubated at 37°C overnight.

Preparation of plasmid DNA.

Plasmids were purified from bacterial cultures using either QIAGEN Plasmid Mini Kit or QIAGEN Plasmid Maxi Kit according to manufacturer's instructions.

DNA manipulation

Restriction digests carried out in 20 μ L (analytical) or 50 μ L (preparative) volumes. Amounts of DNA were 0.5-3 μ g. Single and double digests were done according to recommendations from restriction enzyme supplier using provided buffers (New England Biolabs). Incubation times – 1-2 hours. Where necessary, overhangs were blunted using large (Klenow) fragment of DNA polymerase I, according to manufacturer's instructions (NEB). To prevent self-circularization of digested plasmid DNA, 5'-termini were de-phosphorylated using calf intestinal alkaline phosphatase according to manufacturer's instructions (NEB). Directly after all necessary DNA manipulations were finished, fragments were purified from agarose gels using QIAquick PCR Purification Kit or QIAquick MinElute PCR Purification Kit. Purified fragments were used at 1:3 (sticky ends) or 1:10 (blunt ends) molar vector:insert ratios for ligation in 10 μ L, using 1 μ L of T4 DNA ligase and supplied buffer (NEB). Self-ligation control (ligation without insert) was set up in parallel using the same amount of vector as in test reaction. Ligation was routinely carried out overnight at 16°C followed by inactivation at 70°C for 15 minutes. 1-2 μ L of ligation mix was used to electroporate competent cells.

High fidelity PCR

DNA fragments for cloning purposes were amplified using Phusion® High Fidelity polymerase, using HF reaction buffer. Reactions carried out in presence of 0.25 μ M primers, according to manufacturer's recommendations. Routinely, 36 cycles of amplification were used, while annealing temperature and time varied with melting temperature of primers. PCR products were run on agarose gels and purified either using QIAquick PCR Purification Kit or QIAquick MinElute PCR Purification Kit.

Colony PCR

Screening for insert-containing clones was done using either restriction digest or colony PCR. The latter was carried out as follows: master mix, consisting of 2U Taq polymerase, 1X Thermopol buffer (NEB), 250 μ M dNTPs, 0.5 μ M primers, and 8.25 μ L H₂O per reaction was dispensed in 0.2 mL PCR tubes. Well isolated colony was picked with pipette tip and first streaked onto fresh LB-agar plate and then dipped into PCR tube. PCR was carried out for 36 cycles, annealing temperature varied for different primer pairs

Agarose gel electrophoresis

Agarose solutions (0.8% - 2.5%) were prepared by boiling agarose powder in TBE buffer. Ethidium bromide (0.01%, v/v) was added to the solution before polymerization. Gels were polymerized at room temperature for a minimum of 40 minutes. DNA samples mixed with 6X loading dye were loaded into wells and separated at 100-120V until Orange G dye reached the bottom of the gel. DNA visualized and documented using 302 nm UV light. For excision of fragments, DNA was visualized using 460 nm blue light (Dark Reader™, Clare Chemical Research).

Sequencing of DNA fragments

was done by the core facility of the MPI of Biochemistry, Martinsried

III.2.2. Mammalian cell culture methods

General procedures

All mammalian cells were incubated at 37°C, 10% CO₂. Cell work was carried out in a biosafety level S1 laboratory using sterile laminar flow cabinets. For cell counting, improved Neubauer chamber (hemacytometer) was used. For freezing, cells were re-suspended in freezing medium, aliquoted into CryoTube™ vials and deposited at -80°C in isopropanol chambers. 24-48 hours later vial were transferred to liquid nitrogen for long term storage. Thawing of cells was done in water bath set at 37°C for 2-3 minutes.

Introduction of nucleic acids into the cells

Lipofection

Transient transfections for reporter assays (luciferase assay) were done using Lipofectamine® reagent as described previously (Posern, 2004). 35000 cells in every well of a 12-well plate were seeded the day before transfections. 100 μ L complexes were prepared using OPTI-MEM medium with 2 μ L of lipofectamine reagent and 500 ng of DNA (20 ng p3D.A reporter, 50 ng ptkRL reporter, plus co-transfected construct or empty vector up to 500 ng). Following 20 minutes incubation at room temperature, complexes were added to wells with 0.5 mL OPTI-MEM. 5 hours later, medium was changed to starvation medium for 16-24 hours. Stimulations were done with 15% FBS for 7 hours.

Other transient transfections were done using Lipofectamine® 2000 according to manufacturer's instructions.

Transient transfections of siRNAs were carried out using Lipofectamine® RNAiMAX, according to manufacturer's protocol. Briefly, 40000 cells were seeded in 12-well plates, 250000 cells seeded into 6-cm dishes. For 12-well plates, 30 pmol siRNA and 3 µL Lipofectamine were used to make complexes. For 6-cm dishes, 80 pmol and 10 µL Lipofectamine were used.

Retroviral transfections

First, packaging line Phoenix E was transiently transfected with pLPCX plasmids using calcium phosphate method (Sambrook, 2001). Briefly, 15×10^6 cells were seeded into 15-cm dishes 24 hours before transfection. One hour before transfection, medium was replaced with 15 ml fresh medium containing 25 µM chloroquine. For each transfection, 1 mL 250 mM CaCl_2 was mixed with 40 µg of plasmid DNA. To the mix, 1 mL of 2X BBS solution was added dropwise while vortexing. Mixture incubated for 20 minutes at room temperature and added to the dishes. Packaging cells incubated at 3% CO_2 , 37°C for 24 hours. Next day, medium changed to fresh medium without antibiotics and cells incubated for another 24 hours at 7% CO_2 , 32°C to produce viruses.

One 15-cm dish of virus-producing packaging line was used to infect NIH 3T3 cells in 6-cm dish. 1.5×10^5 NIH 3T3 cells were seeded one day before infection and medium was changed to fresh DMEM supplemented with 8 µg/mL polybrene just before infections. Supernatant from transfected packaging cells was concentrated using Vivaspin 20 centrifugal concentrators (Sartorius, Göttingen) down to 1 -2 mL and used to infect NIH 3T3 cells. Packaging line was supplemented with fresh medium again and second round of infections repeated 8 hours later.

Generation of stable cell lines

Cells stably expressing FUCCI markers and H2B-GFP were generated following transfection with Lipofectamine® 2000. NIH-3T3-FUCCI cells were FACS-sorted as follows: first two sorts – mAG-positive cells only, next 4 times – mAG- and mKO2-double positive cells. Between sorts and afterwards cells were maintained in medium supplemented with 250 µg/mL of G418. NIH 3T3-H2BGFP cells were sorted 2 times for GFP-positive cells. Between sorts and afterwards maintained in 0.2 µg/mL puromycin. NIH 3T3-shMAL and NIH 3T3 pSUPER empty vector cell lines were generated following retroviral transfection with pSUPER.retro.puro-shMAL or pSUPER.retro.puro empty vector and selection with 1 µg/mL puromycin for 3 weeks. These cell lines were further sub-cloned to produce monoclonal cell lines by re-seeding cells at 1:30 dilution and expanding individual clones after 2 weeks of selection. Both polyclonal pool and clones were afterwards maintained in medium supplemented with 0.2 µg/mL of puromycin. Stable NIH 3T3 cell lines expressing Tet-inducible actin^{wt} or pcDNA.TO empty vector were maintained in medium supplemented with 2.5 µg/mL blasticidin and 150 µg/mL zeocin.

Proliferation assays

For MTT assay, cells were seeded into 96-well plates in quadruplicates 18 hours post-transfection and incubated for further 15 hours before the first time point. 1 hour before the time point, 40 µL of MTT solution (5 mg/mL in PBS) was added to the well and cells incubated for 1 hour. Medium was removed and MTT Formazan crystals dissolved in 150 µL of DMSO. Absorbance at 560 nm measured using Labsystems Multiscan RC (Thermo Scientific).

For cell counting, cells were seeded into 12-well plates in duplicates (10000 for 10% FBS-containing medium, 35000 for 0.5% FBS-containing medium). At the indicated time points, cells were trypsinized and counted using improved Neubauer chamber. 9 quadrants counted per sample.

III.2.3. Protein analytical methods.

Cell lysis for Western blotting

Cells were washed with ice-cold PBS in plates and ice-cold RIPA buffer, supplemented with 1X Complete™ protease inhibitor cocktail, added to the cell monolayer. Lysate scraped with rubber policeman and transferred into Eppendorf tubes. Before measuring concentration, lysate were pre-cleared by centrifugation at 14000 RPM for 10 minutes at 4°C.

Co-immunoprecipitation

For mass-spectrometry analysis of G-actin interacting proteins, Tet-inducible cell lines were stimulated with 1 µg/mL doxycycline for 24 hours and then serum starved in starvation medium (0.5% FBS) supplemented with doxycycline for another 18 hours. For every co-IP sample 2 15-cm dishes of ca. 70% confluent cells were used. After stimulation with 15% FBS for 30 minutes, cells were scraped from the dishes in 1 ml of PBS and pellets lysed in 1 mL of RIPA buffer supplemented with protease inhibitor cocktail. After centrifugation at 14000 RPM, 4°C for 20 minutes, 950 µL of lysates were incubated with 25 µL packed volume of anti-FLAG® M2 magnetic beads for 3 hours at 4°C. Beads were washed 3 times with 700 µL of lysis buffer and immunoprecipitated proteins eluted from the beads with 25 µL of 4x SDS-PAGE sample loading buffer (Invitrogen). Eluates from appropriate samples were mixed and separated on the gradient acrylamide gels.

Determination of protein concentration

Protein concentration measured using Micro BCA™ protein assay kit (Pierce) according to manufacturer's instructions using 96-well plate format. Briefly, for every measurement, standard curve was set up using provided BSA solution. In parallel, 2 µL of protein lysates were added to 100 µL of BCA reagent in triplicates and incubated for 30 minutes at 37°C. Absorption was measured at 595 nm using microplate reader. Protein concentration was calculated from standard curve using 2nd power polynomial equation.

SDS-polyacrylamide gel electrophoresis

Proteins were separated using PAGE according to Laemmli, 1970 with minor modifications. Stacking gel was 5% acrylamide-bis (37.5:1) solution in 127 mM Tris-HCl pH 6.8, 0.1% (w/v) SDS, 4.5% (v/v) glycerol and 0.1% (w/v) APS. Separating gel contained 8-12% acrylamide in 377 mM Tris-HCl pH 8.8, 0.1% (w/v) SDS and 0.1% (w/v) APS. 0.1% (v/v) TEMED was used for polymerization. Equalized amounts of lysates were mixed with 4X sample loading buffer, boiled at 95°C for 5 minutes and separated at 100-150V until bromphenol blue dye front reached the bottom of the gel. For mass-spectrometry analysis, pre-cast gradient (4-12%) NuPAGE® gels were used (Invitrogen). Following separation, gels were either stained with Coomassie using Colloidal Blue staining kit (Invitrogen) or used for western blotting.

Western blotting

Proteins were transferred to PVDF membrane using Mini Trans-Blot Cell (Bio-Rad) according to manufacturer's recommendations. Transfer was done at constant 100V for 1.5 hours. To monitor transfer efficiency, membranes were stained with Poceau to visualize proteins.

Immunoblot detection

After the transfer, membranes were blocked with 5% non-fat milk in TBS/T for 1 hour at room temperature. After blocking, membranes were incubated with primary antibodies in blocking solution overnight at 4°C. Next day, membranes were washed 3 times (5 minutes each) with TBS/T and

incubated with secondary antibodies in blocking solution for 1 hour at room temperature. For HRP-conjugated primary antibodies incubation was 1 hour at room temperature. After washing 3 times (10 minutes each) with TBS/T, membranes were incubated with Western Lightning ECL reagent for 1 minute. Signal was captured using cooled CCD-cameras on gel documentation systems (FujiFilm of Bio-Rad). When necessary, membranes were stripped using Restore Western Blot stripping buffer and the whole procedure from the blocking step onward was repeated.

III.2.4. Quantitative real-time PCR

Total RNA was isolated using QIAGEN RNeasy Mini Kit according to manufacturer's instructions. cDNA was synthesized from 1 µg of RNA and oligo-dT primer using Verso™ cDNA kit according to manufacturer's protocol. For qRT-PCR, cDNA was diluted 1:5. Reaction setup was as follows: 7.5 µL of SYBR Green Master mix, 0.25 µM gene-specific primers and H₂O to 12.5 µL. 2.5 µL of diluted cDNA added to the mix to complete 15 µL reaction volumes. PCR reaction was carried out on either StepOnePlus or LightCycler 480 II instruments. Cycling conditions were 95°C for 10 seconds, 60°C for 30 seconds. Melting curves were routinely generated from every reaction to access the specificity of PCR. Relative concentrations were calculated using $\Delta\Delta C_t$ method in qBase software (Hellemans, 2007).

III.2.5. Luciferase reporter assay

The luciferase reporter assay was carried out using Dual-Glo™ Luciferase Assay Kit (Promega). Cells were washed twice with ice-cold PBS and lysed by incubation in 100 µL of Passive Lysis Buffer (PLB) per one well of 12-well plate for 15 minutes. Lysates were transferred in eppendorf tubes and cleared by centrifugation at 13000 RPM for 5 minutes. 20 µL of the supernatant was transferred into a well of a white-walled 96 well microtiter plate and mixed with 45 µL LARII solution. Luminescence readings were collected and 45 µL of Stop & Glow reagent supplemented with Stop & Glow substrate was added to the well to stop the Firefly reaction and start Renilla luminescence emission. Luminescence was read again. Reporter activity was calculated by normalizing Firefly luminescence values with Renilla luminescence values

III.2.6. Cell cycle analysis

Propidium iodide staining was done according to Riccardi, 2006. Briefly, 18 hours post-transfection, cells were split into 6-cm plates and grown for indicated periods of time. Cells were collected by trypsinization and fixed with 70% ethanol. After washing with PBS, cells were stained for 30 min with 50 µg/mL propidium iodide in PBS, supplemented with 200 µg/mL RNase A. BD FACSCalibur or BD Accuri C6 (BD Biosciences) were employed to measure fluorescence from 20000 cells per sample. Data was analysed using FlowJo software v7 (TreeStar, USA). DNA histograms were generated by gating on single cell events and cell cycle phases de-convoluted using built-in Dean-Jet-Fox algorithm. BrdU staining was carried out using FITC BrdU Flow kit (BD Pharmingen) according to manufacturer's protocol. Briefly, cells were pulse-labeled with 10 µM BrdU for 20 minutes in medium, trypsinized and fixed. After DNA digestion, cells were stained with FITC-labeled anti-BrdU antibody for 20 min, co-stained with 7-AAD and analyzed with FACSCalibur or Accuri C6 flow cytometers. 50000 events collected per sample and dot plots of single events generated with FlowJo software.

III.2.7. Immunofluorescence staining

Cells were grown on uncoated glass coverslips in 12-well dishes. Prior to fixation, the cells were washed twice in PBS on ice. Then fixed in 4% PFA for 10 – 15 minutes at RT and permeabilized for 10 minutes in 0.2% Triton X-100 in PBS. Unspecific epitopes were blocked by incubation for 1 hour in blocking solution. Coverslips incubated with primary antibodies in blocking solution for 1 hour at room temperature, with phalloidin or nuclear dyes in PBS for 20 minutes at room temperature. Secondary antibodies in blocking buffer were applied for 1 hour at room temperature. Afterwards coverslips were washed 2 times with PBS, once with bi-distilled water and mounted onto glass slides with Mowiol reagent supplemented with 2.5% DABCO. Pictures acquired in MetaMorph of AxioVi-

sion software using either Zeiss Observer.A1 or Z1 microscopes with Plan-Apochromat 20x/0.8 or Plan-Apochromat 63x/1.40 Oil objectives.

III.2.8. Chromatin immunoprecipitation

2×10^7 NIH 3T3 cells for each immunoprecipitation reaction were fixed with 1% formaldehyde in growth medium for 10 minutes at room temperature. Cross-linking was stopped with 125 mM glycine for 5 minutes. Cells were washed twice with PBS and scraped in 3 ml of PBS into eppendorf tubes. Cell pellets were lysed with 3 mL Farnham lysis buffer (20 mM Tris-HCl, pH 8.0, 85 mM KCl, 0.5% Triton X-100) for 5 minutes on ice and nuclei pelleted by centrifugation at 500xg, 4°C, 5 minutes. Nuclear pellet was lysed using 1 mL of CHIP RIPA buffer (1% Triton X-100, 0.5% Na-deoxycholate, and 0.1% SDS in 1 X PBS) for 20 minutes on ice. Lysates were sonicated on Bandelin HD3100 sonicator equipped with MS72 tip with the following settings: 80% amplitude, 10 sec pulse, 30 sec pause. Every sample was sonicated for a total of 24 cycles (4 minutes of sonication). Sheared chromatin was pre-cleared by centrifugation at 14000 RPM, 4°C for 10 minutes. 40 μ L of Dynabeads Protein G were pre-coupled with anti-MAL antibody (#79, 300 μ l), anti-SRF antibody (G-20, 5 μ g) or anti-NF2 antibody (5 μ g) by incubating beads and antibodies in total volume of 500 μ L (PBS) for 6 hours. 850 μ L of sheared chromatin was mixed with antibody-coupled Dynabeads and incubated overnight on a rotating wheel at 4°C. After incubation, beads were washed 5 times with LiCl buffer (100 mM Tris-HCl, pH 7.5, 500 mM LiCl, 1% Tritox X-100, 1% Na-deoxycholate) and once with TE buffer. Complexes eluted with 100 μ L of elution buffer (0.2% SDS, 0.1M NaHCO₃) at 65°C for 30 minutes. Eluates and separately collected input chromatin samples were subjected to the cross-link reversal by supplementing 100 μ L of sample with 5 μ L of 5M NaCl, 1 μ L of Proteinase K and 1 μ L of RNase A. Samples were first incubated at 37°C for 1 hour and then at 65°C overnight. DNA purified using QIAGEN PCR purification kit according to manufacturer's instructions. Eluted in 100 μ L of EB buffer and used for qualitative real-time PCR according to standard protocol. Results were calculated as percent of input chromatin according to the formula $2\% \times 2^{(C_t^{\text{INPUT}} - C_t^{\text{IPsample}})}$, where 2% is the percentage of chromatin purified as input sample (for example, for 850 μ L of chromatin used in IP, 17 μ L of input chromatin is needed to make up 2%).

III.2.9. Live cell microscopy

Cells were seeded into non-coated, 4-chambered Cellview™ glass bottom dishes (Greiner Bio-One) 18 hours post-transfection and incubated for 6 hours before live imaging was started. During live imaging, cells were maintained at 37°C, 10% CO₂ in a Carl Zeiss Observer.Z1 microscope equipped with incubator XL S1 (Pecon), TempModule S, CO₂ module S and heating unit XL S. Images captured every 5 min for 48 to 65 hours with AxioCam MRm camera and Plan-Apochromat 10x/0.45 objective (FUCCI markers) or Plan-Apochromat 20x/0.8 objective (H2BGFP). GFP and mAG fluorescence imaged using Zeiss Filter Set 38HE (BP470/40, FT 495, BP 525/50), mKO2 fluorescence imaged using Zeiss Filter Set 43HE (BP 545/25, FT570, BP 605/70). Exposures were 200 ms for mAG, 400 ms for mKO2 and 90 ms for GFP. Images were saved with AxioVision 4.7 software. For analysis, TIFFs were exported to ImageJ software and manually analyzed for individual cell phase duration, total cell cycle length, duration of mitosis.

III.2.10. Mass-spectrometry

SILAC-based mass-spectrometry analysis was done according to Ong, 2007. Briefly, cells were labeled with heavy and light amino acids (see above) for at least 6 generations. After determining that the labeling efficiency was greater than 99%, cells were serum-starved, stimulated and subjected to co-immunoprecipitation. colP samples were separated using PAGE and protein samples for analysis prepared using in-gel digestion protocol. Briefly, every lane of the gel was cut into 6 slices and each slice was further cut into small cubes, with the side of approximately 1mm. Gel cubes were washed with 50 mM ammonium bicarbonate (ABC), 50% acetonitrile until fully de-stained. Gel cubes were further dehydrated with acetonitrile and re-hydrated with 50 mM ABC with 10 mM DTT.

Proteins were reduced at 56°C for 1 hour. Resulting thiol groups were alkylated by adding 55 mM iodoacetamide in 50 mM ABC for 1 hour at 25°C in the dark. After washing, gel cubes were dehydrated in acetonitrile and dried in vacuum concentrator. Each sample was re-hydrated using 50 mM ABC solution containing 0.4 µg trypsin. Digestion was carried out at 37°C overnight. Peptides were extracted from the gel cubes 2 times with 30% acetonitrile-3% trifluoroacetic acid (TFA) and 2 times with 100% acetonitrile. All extracts were combined and acetonitrile was evaporated in a vacuum concentrator. Samples were de-salted using home-made reverse phase C18 STAGE Tips (Rappsilber, 2003) and eluted peptides were used for mass-spectrometry analysis. All peptides were separated by on-line reverse phase nano-liquid chromatography (nano-LC) using Agilent 1100 nanoflow system connected to LTQ-Orbitrap mass spectrometer, equipped with nano-electrospray ion source (Proxeon Biosystems). Loaded peptides were eluted with 140-min gradients from 5-40% acetonitrile in 0.5% acetic acid. Data acquisition performed using Xcalibur 2.0 software in positive ion mode. Identification of peptides and downstream analysis was done using MASCOT search engine, MSQuant software and custom R scripts. All analysis performed by collaborators.

IV. RESULTS

Novel targets of MRTF-SRF pathway: validation using chromatin immunoprecipitation.

IV.1.1. Identification of G-actin regulated genes: combination of actin-binding drugs and microarray analysis.

Transcription via MRTF-SRF pathway is regulated through direct physical interaction between MRTF co-activators and monomeric G-actin and therefore depends on the availability of G-actin pool in a cell. Interfering with actin polymerization dynamics by using cytochalasin D and latrunculin B have antagonistic effects on the MRTF-SRF pathway. Used at certain concentrations, cytochalasin D potently activates MRTF-mediated transcription, while pre-treatment with latrunculin B quenches the effect of cytochalasin D and represses the pathway further, past the level of background transcription (Descot *et al.*, 2009). Our group previously employed this phenomenon to identify genes transcriptionally regulated by G-actin dynamics on a whole-genome scale. RNA isolated from NIH 3T3 cells that were treated with cytochalasin D alone or in combination with latrunculin B, was analyzed using Affimetrix Gene Chip arrays. Genes up-regulated by cytochalasin D, but repressed by double treatment with cytochalasin D and latrunculin B were considered as putative G-actin-regulated targets and analyzed further. For detailed description of the screening approach and full list of identified targets, see (Descot *et al.*, 2009) and GEO dataset GSE17105.

IV.1.2. Chromatin immunoprecipitation protocol

The focus of several projects in our group was to characterize certain target genes from the microarray screen as direct MRTF-SRF targets. The most conclusive approach to show direct physical recruitment of a transcriptional co-activator to the promoter of a target gene is to employ chromatin immunoprecipitation (ChIP). My very first task was to establish a reliable ChIP protocol and use it to confirm the binding of MRTFs and SRF to the promoter elements of putative target genes. Various parameters of the protocol have been tested: initial cell number, sonication versus micrococcal nuclease digestion, sonication duration, immunoprecipitation conditions, various MRTF antibodies, washing conditions and DNA purification methods. Optimized protocol used 1.5×10^7 NIH 3T3 cells, sonication of the genomic DNA in 1 ml of lysis buffer to the fragment sized between 300 and 1000 bp (Figure IV-1) and home-made anti-MRTF antibody #79. These conditions allowed for effective DNA shearing for better ChIP resolution and, at the same time, MRTF protein integrity was not compromised (Figure IV-2). Immunoprecipitation efficiency was adequate when using anti-MRTF antibody #79 (Figure IV-3), while other antibodies tested either did not work with the protocol or gave inferior results in qPCR (data not shown). Antibody #79 is polyclonal rabbit serum which recognized both MRTF-A and MRTF-B. Therefore, in ChIP experiments presented here it is technically not possible to discriminate between the two isoforms. Promoters of the known MRTF-SRF targets Cyr61 and SRF itself were used as positive controls to monitor the efficiency of the procedure. In control NIH 3T3 cells I consistently observed strong inducible recruitment of MRTFs to the promoters of Cyr61 and SRF upon stimulation with cytochalasin D. At the same time, in cells stably expressing shRNA against MRTFs this recruitment was strongly impaired (Figure IV-4). I employed this established ChIP method to probe the recruitment of SRF and MRTFs to certain genes that scored positively on Affimetrix microarray.

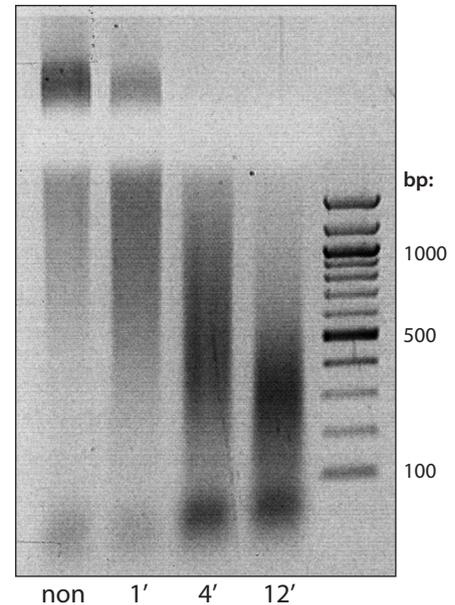

Figure IV-1: *Optimisation of chromatin shearing for ChIP.* NIH 3T3 cell lysates were sonicated for 0, 1, 4 or 12 minutes. 5 μ g of total DNA was separated on 1% agarose gel. 4 minutes was used for subsequent experiments. Marker - log 2 ladder (NEB)

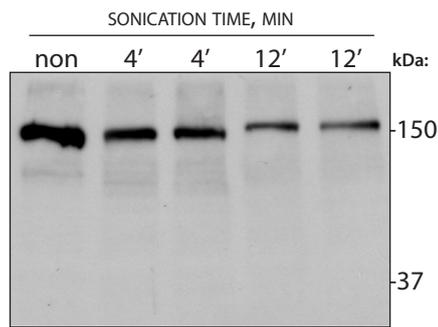

Figure IV-2: *MRTF-A/B protein integrity check following sonication.* Western blot showing MRTF-A/B in NIH 3T3 lysates after chromatin shearing for indicated times. Sonication to some extent reduces amount of protein in lysates, but the integrity is not compromised.

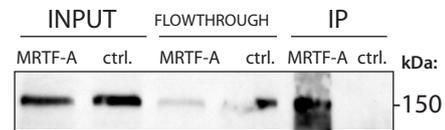

Figure IV-3: *Immunoprecipitation efficiency of MRTF-A/B using antibody #79 and ChIP protocol.* Western blot showing MRTF-A/B IP'd using anti-MRTF-A/B #79 antibody and non-specific control antibody. IP efficiency is greater than 90%. Control Ab does not precipitate MRTF-A/B

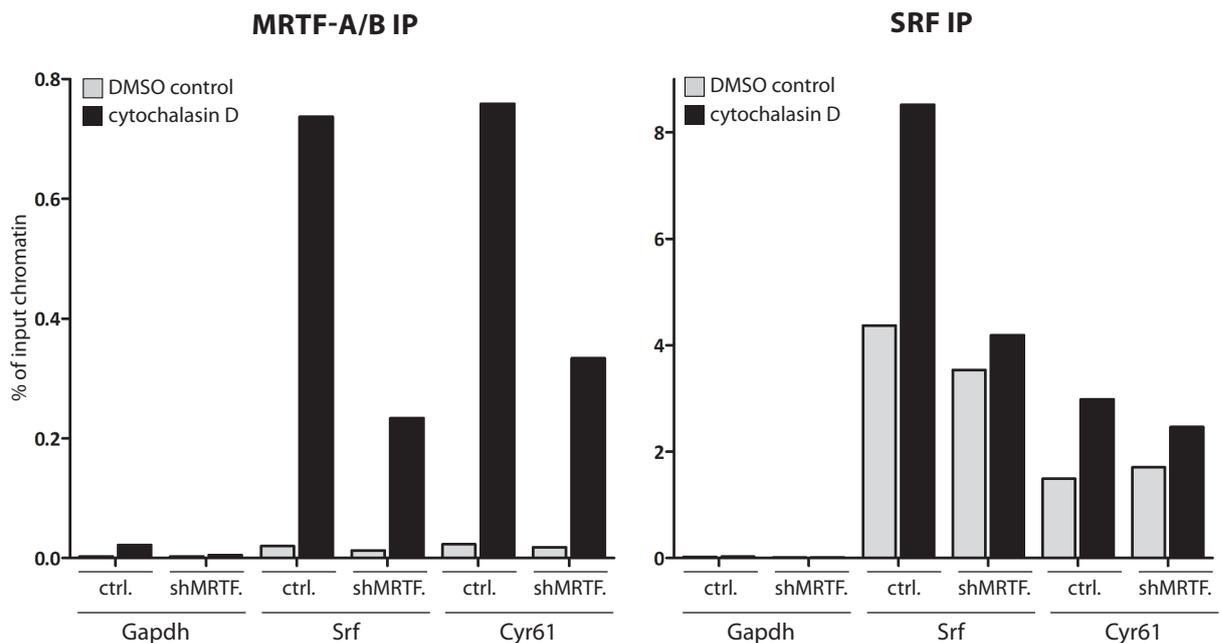

Figure IV-4: *Chromatin immunoprecipitation efficiency and specificity.* NIH 3T3 cells stably expressing empty pSuper.retro.puro (ctrl.) or shRNA against MRTF-A/B were serum starved for 24 hours and either stimulated with 2 μ M cytochalasin D or left untreated (DMSO control). Following 30 min of stimulation, cells were subjected to chromatin immunoprecipitation using optimised protocol. Promoter fragments from known SRF target genes Srf and Cyr61 were amplified using real-time PCR. Gapdh promoter region served as negative control. MRTF-A/B knockdown cells display decreased enrichment of MRTFs on the promoters. Background binding of SRF is not affected by the knockdown. $n=7$

IV.1.3. Mig6/Errf1

Mig6 is a negative regulator of EGFR signaling. It prevents EGFR dimer formation, thereby blocking the downstream signaling events (Zhang *et al.*, 2007). Promoter analysis done previously (Descot *et al.*, 2009), identified a putative SRF binding site at position -260 from the transcription start site. The sequence of this CarG-like element – CCTTCTAAGG – deviates from the consensus by the presence of base C in the A/T-rich core of the motif. Nevertheless, luciferase assays have established that a deletion of this CarG-like element leads to the complete block of transcription from the promoter fragment -392..-96. qPCR primers for amplification of the promoter fragment around the position -260 have been designed previously. ChIP experiments have established that, indeed, SRF is bound to this particular CarG-like element in serum-starved condition as well as upon stimulation with 15% fetal bovine serum. MRTFs, on the other hand, were only marginally bound to the same locus in the absence of stimulus, but were recruited to the promoter upon stimulation (Figure IV-5). Of note, the absolute recruitment levels of SRF and MRTFs to the Mig6 promoter were lower than those for the control SRF promoter, which potentially reflects the non-consensus nature of the CarG-like element in Mig6 promoter.

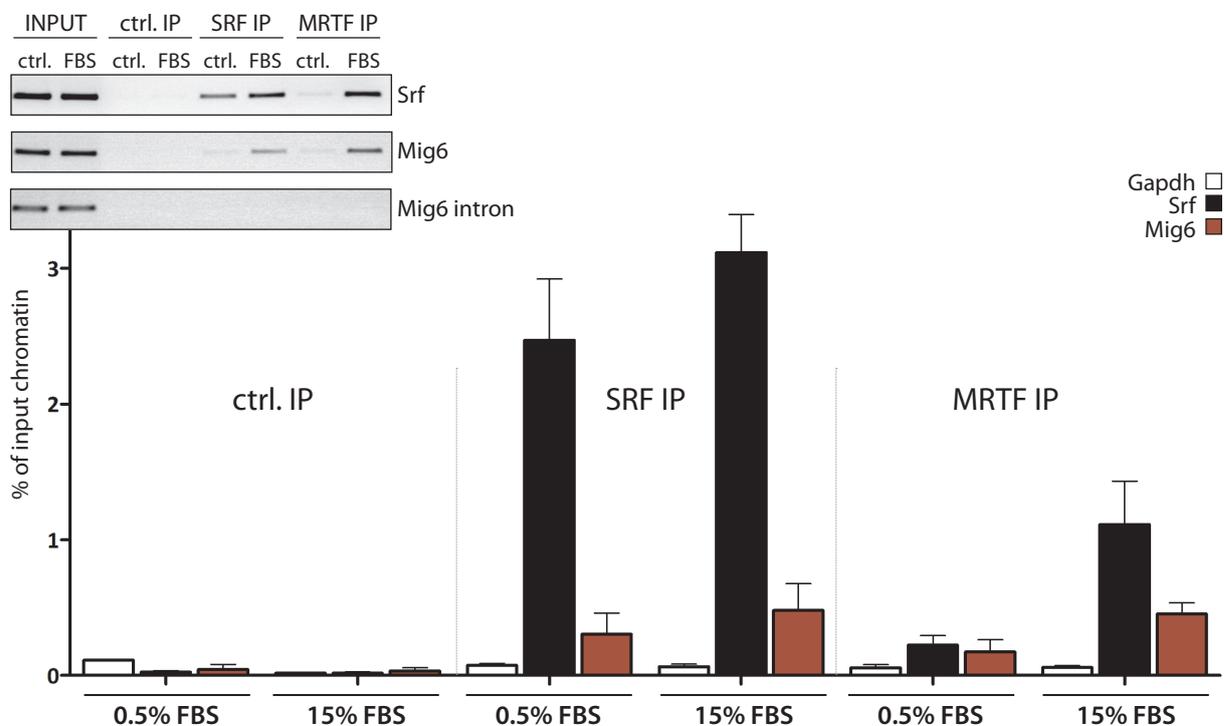

Figure IV-5: Mig6 chromatin immunoprecipitation. CarG-like element in Mig6 promoter (-260) is bound by SRF with or without stimulation with 15% FBS for 30 min. MRTF-A/B are recruited to Mig6 promoter upon serum stimulation. Positive control Srf demonstrates similar behavior, although enrichment is stronger. Inset shows representative agarose gels with an additional negative control - intronic region of Mig6 gene. Real-time PCR, $n=3$, bars - SEM.

IV.1.4. Eplin-alpha

Epithelial Protein Lost in Neoplasm alpha has been recently established as an important component of adherens junctions in epithelial and endothelial cells with the suggested role in stabilizing capillary structures. It was proposed to act as a tether between VE-cadherin-catenin complexes and actin cytoskeleton, providing a link between the adherens junctions and intracellular cytoskeletal network (Chervin-Pétinot *et al.*, 2012). Analysis of the eplin-alpha promoter was done previously (Leitner *et al.*, 2010). In the first 2000 bp upstream from the transcription start site there are 2 potential SRF-binding sites, one of them is a consensus CarG box at -124 bp, and the second is a CarG-like element at position -1050. Luciferase assays have established that the 2000 bp long fragment of the immediate promoter was responsive to the serum and cytochalasin D stimulation, while latrunculin B had a repressing effect on the reporter. Deletion of the CarG-like element at position -1050 did not have an effect on the transcription, indicating that the consensus CarG box at position -124 is responsible for the transcription. For ChIP experiments I used qPCR primers amplifying

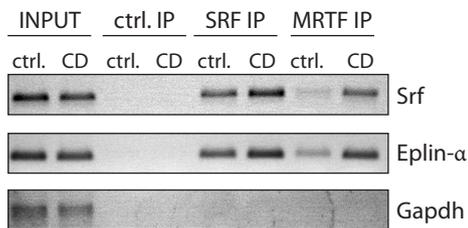

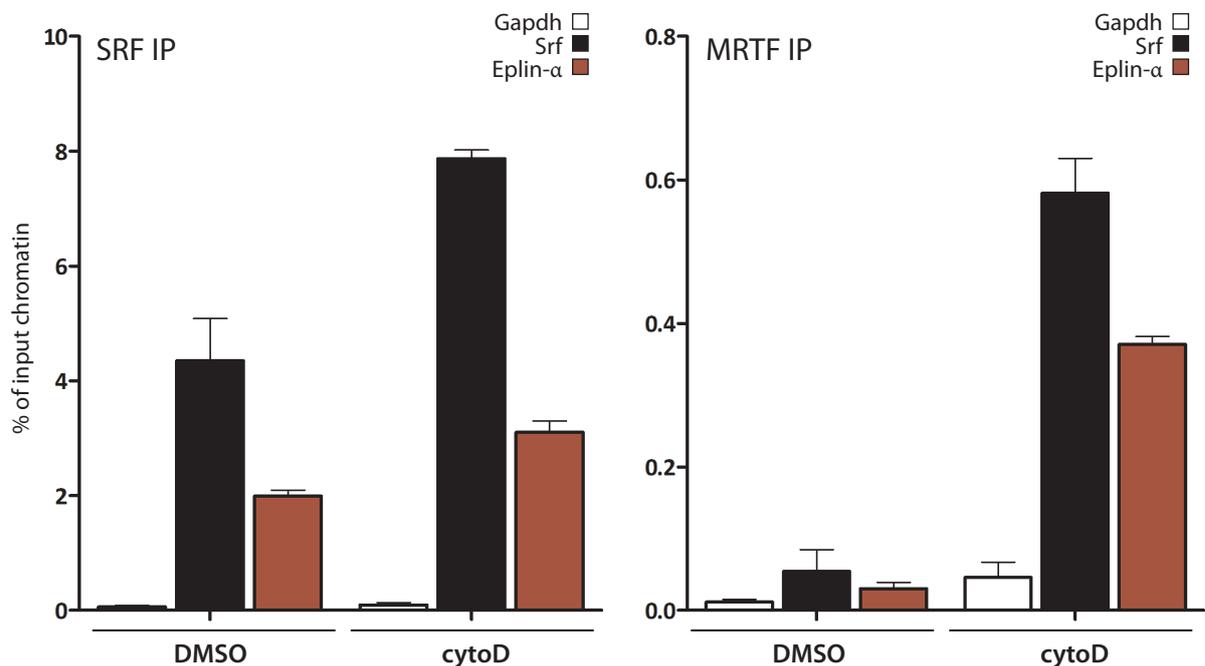

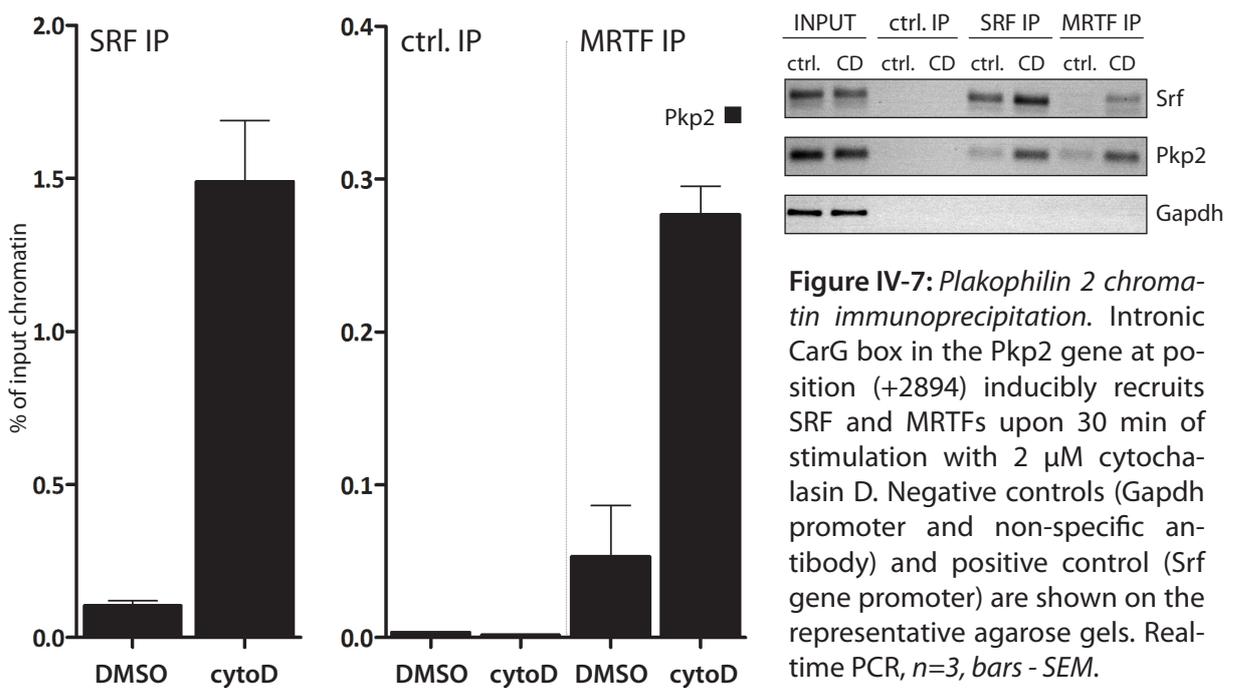

Figure IV-6: *Eplin-α* chromatin immunoprecipitation. Consensus CarG box at position -124 in *Eplin-α* promoter is bound by SRF. MRTF-A/B are recruited to this element upon stimulation with 2 μ M cytochalasin D (30 min time point). Positive control, promoter region of *Srf* gene demonstrates similar behavior. Immunoprecipitation with non-specific antibody is shown only on the representative agarose gels. Real-time PCR, $n=3$, bars - SEM.

ing bases -178.-15 of the immediate promoter region of eplin-alpha gene and stimulation with cytochalasin D. Results (Figure IV-6) unequivocally place eplin-alpha into the cluster of SRF-MRTF-regulated genes. Recruitment pattern was similar for MRTFs, but I notice that SRF binds eplin-alpha promoter to a lesser extent with almost no observable increase in binding upon stimulation with cytochalasin D.

IV.1.5. Plakophilin 2, Pai-1, Fhl1

Plakophilin 2 is a member of the large armadillo plaque proteins family. Is it localized to desmosomes of all proliferating epithelial cells and their derivative (e.g. tumors) (Bass-Zubek *et al.* 2009) and in the junctions connecting cardiomyocytes (Franke *et al.*, 2006). It has a critical role in heart development, since its knockout in mice and zebrafish results in lethality due to defects in heart formation (Grossmann *et al.*, 2004, Moriarty *et al.*, 2012).

Surprisingly, *pkp2* gene does not contain consensus CarG boxes in the immediate promoter up to 2000 bp upstream from the transcription start site. Several CarG-like elements found in this area did not recruit SRF or MRTFs to the corresponding promoter regions (data not shown). Further analysis (performed by Laura Leitner) has identified a consensus CarG box in the first intron of the gene at the position +2894 downstream from the transcription start site. ChIP using primers amplifying this region have confirmed an inducible binding of both SRF and MAL to the intronic CarG box (Figure IV-7) Intriguingly, unlike in control SRF promoter, where SRF is constantly bound to the DNA even in the absence of stimulus, SRF did not

occupy p_{pk2} promoter in the serum-starved cells, but got recruited upon serum stimulation.

Additional G-actin regulated genes that have been characterized as SRF-MRTF targets – plasminogen activator inhibitor 1 (Pai-1) and four and a half LIM domains protein 1 (Fhl1) – were subjected to promoter analysis using chromatin immunoprecipitation. None of the tested CarG boxes or CarG-like elements within 2000 bp immediate promoters of both genes could show binding of SRF or MRTFs (data not shown), indicating that other binding sites might exist.

Anti-proliferative effect of MRTF-A in NIH 3T3 cells: apoptosis connection?

The fact that over-expression of constitutively active MRTF-A causes extensive cell death and is incompatible with clonal selection has been previously established by our group (Descot *et al.*, 2009). Moreover, this toxic effect positively correlated with the form of MRTF-A being over-expressed, i.e. full length protein with three intact RPEL motifs had almost negligible effect in retroviral transfections, while MRTF-A lacking first RPEL motif (MALmet), or constitutively active MRTF-A, which have all three RPEL motifs deleted (Δ N MAL), evoked gross enlargement of cells (Figure IV-8) accompanied by drastically increased cytotoxicity (Figure IV-9). Additionally, MRTF-A form that lack both C-terminal transactivation domain (which is indispensable for transcription) and three RPEL motifs had no adverse effects on cell proliferation (Shaposhnikov *et al.*, 2012), supporting the hypothesis that MRTF-A-mediated transcriptional activity is required for the observed effects.

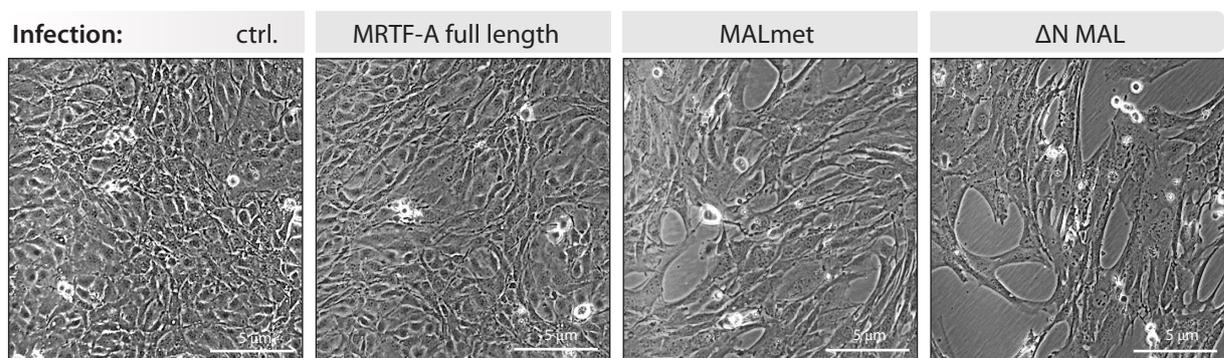

Figure IV-8: Morphological changes in NIH 3T3 cells following MRTF-A over-expression. Cells were infected with MRTF-A constructs using retroviral particles. ctrl. - pLPCX empty vector, MALmet - MRTF-A lacking first RPEL domain, Δ NMAL - MRTF-A lacking all three RPEL domains. Phase contrast pictures of live cells were taken 72 hours post-infection. 10x magnification.

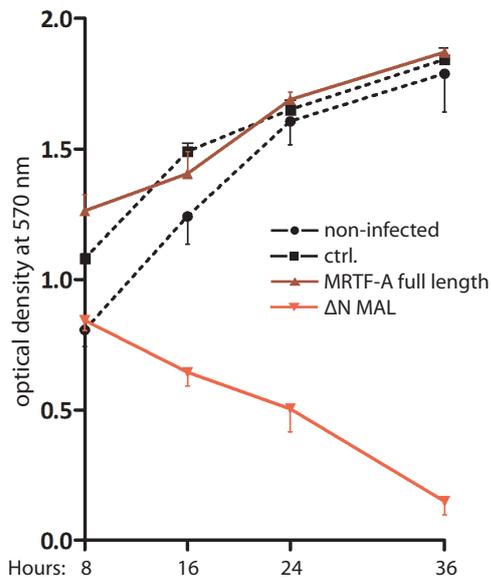

Figure IV-9: Cytotoxic effect of constitutively active MRTF-A. NIH 3T3 cells were infected with the indicated constructs and subjected to MTT assay at the time points shown. ctrl. - empty pLPCX vector. $n=1$, bars - SEM of 3 technical triplicates

pendent increase in annexin V-positive staining (from 11 to 37%), characteristic of apoptotic cells (Figure IV-10). Importantly, a significant population of cells positive for both annexin V and propidium iodide was also detected, signifying the presence of cells with compromised plasma membrane integrity, which could represent either primary or secondary necrosis (Savill *et al.*, 2002, see Box 1). Therefore, these experiments do not eliminate the possibility of apoptosis-independent cell death occurring in parallel with true apoptosis.

Probably the most important hallmark of the classical apoptosis pathway is the activation of caspases (Salvesen & Dixit, 1997, Thornberry & Labeznik, 1998). Both extrinsic and intrinsic apoptosis pathways converge at the step of effector caspase activation: caspase-3 and 7 (reviewed in Tait and Green, 2010). Therefore, I set out to detect active form of the caspase-3 upon overexpression of constitutively active form of MRTF-A in NIH 3T3 cells. Staining with anti-active caspase-3 antibody coupled to phycoerythrin, followed by FACS analysis, have demonstrated that, indeed, a large percentage of MALmet and ΔN MAL overexpressing cells – 41.5% and 56.4% correspondingly – display positive staining for active caspase-3 (Figure IV-11). Of note, weak intensity of the FACS staining prompts to suggest that the activation of caspase-3 in these conditions happens only to a minor extent. Confirming this hypothesis, western blot analysis of total caspase-3 showed that only a small fraction of

Previous experiments with propidium iodide staining have identified an elevated sub-G1 population in MRTF-A over-expressing NIH 3T3 cells (Shaposhnikov *et al.*, 2012), pointing to the activation of classical apoptosis pathway. In order to pinpoint the involvement of apoptosis pathway in MRTF-A induced cell death, I have initially investigated one of the indicator events in the course of apoptosis execution – translocation of phosphatidylserine from the inner side of plasma membrane to the outer layer (Fadok *et al.*, 1992). Annexin V coupled to FITC (Vermes *et al.*, 1995) was used to detect PS in non-permeabilized NIH 3T3 cells transiently over-expressing either full length MRTF-A, or constitutively active MRTF-A (ΔN MAL). Time-course experiments have established that ΔN MAL, but not full length MRTF-A expressing cells display time-

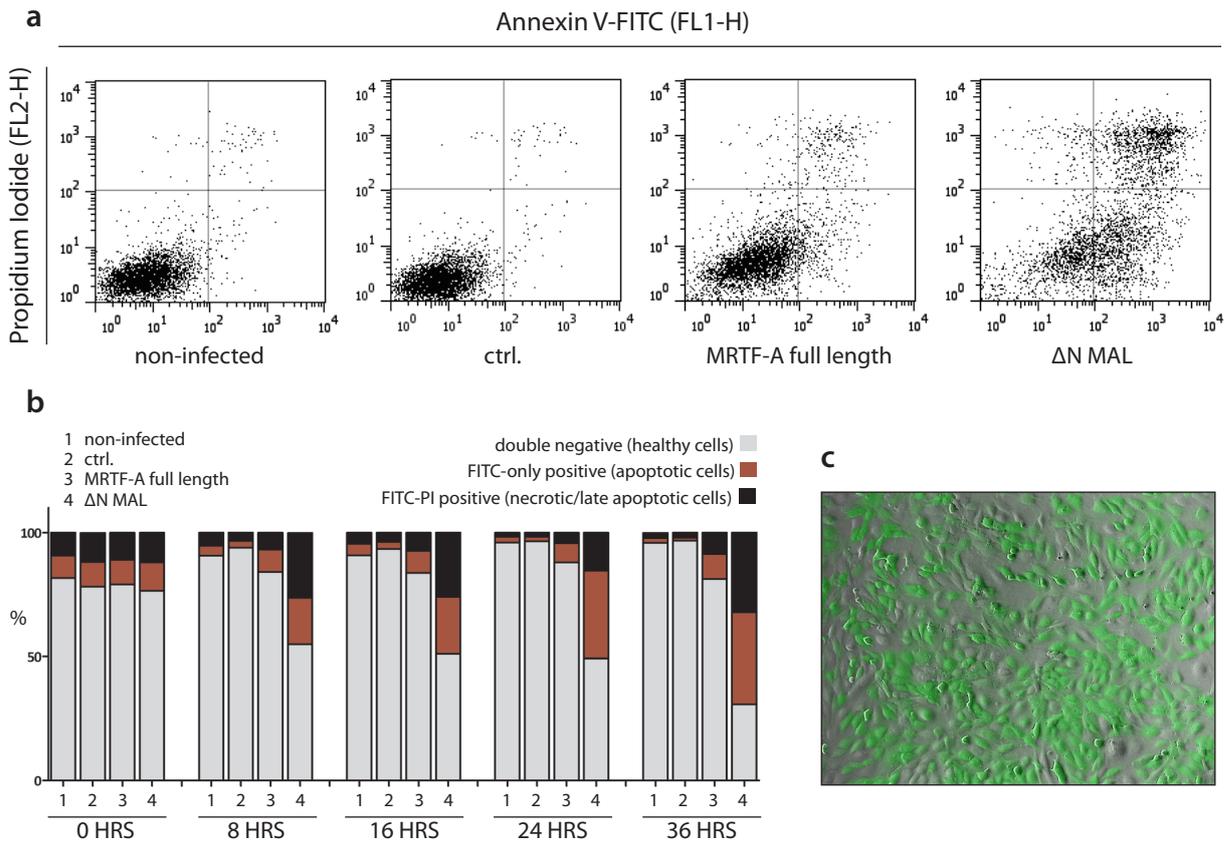

Figure IV-10: Phosphatidylserine switch following MRTF-A over-expression. NIH 3T3 cells were retrovirally infected with MRTF constructs and subjected to annexin V staining. **a.** Representative FACS scatter plots at 36 hours time point. 10000 cells per sample were analysed. Lower right quadrant contains apoptotic cells. **b.** Quantification of a time course of annexin V assay. Gray bars correspond to the lower left quadrant on scatter plot. Red bars - lower right quadrant, black bars - upper right and left quadrants. $n=1$, representative experiment. **c.** Infection efficiency. NIH 3T3 cells retrovirally infected with pLPCX-eGFP in parallel. Picture taken 36 hours post-infection. Overlay of phase contrast and eGFP fluorescence. Infection efficiency >95%.

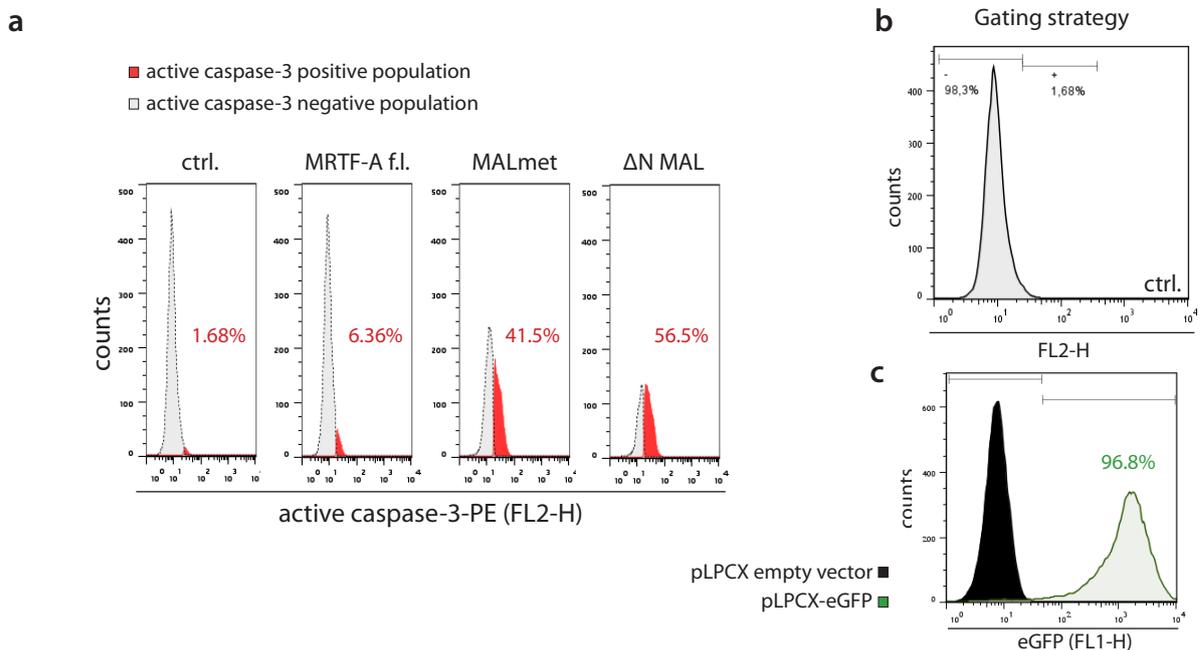

Figure IV-11: *Activation of caspase-3 following MRTF-A over-expression.* NIH 3T3 cells were retrovirally infected with MRTF-A constructs and subjected for active caspase-3 staining at 36 hours time point. **a.** Histograms showing caspase-3-positive and -negative populations in samples. Percentages of positive cells in each sample are indicated. Median FL2-H fluorescence was 8.98 for ctrl. (pLPCX empty vector), 9.31 for MRTF-A full length, 17.15 for MALmet (MRTF-A lacking first RPEL motif) and 21.67 for Δ N MAL. 10000 cells collected per sample. **b.** Gating strategy for histograms shown in a. **c.** Infection efficiency of pLPCX-eGFP vector at 36 hours time point. 96.8% of cells were infected.

caspase-3 is cleaved into the active form (Descot *et al.*, 2009 and data not shown).

To assess the extent to which caspases are responsible for the MRTF-A mediated cell death, I used a broad pan-caspase inhibitor zVAD-FMK (Slee *et al.*, 1996) alongside MRTF-A overexpression. Cells grown for 102 hours after retroviral infections with or without caspase inhibitor showed comparable levels of cytotoxicity (Figure IV-12), giving yet another indication that the role of the caspases (and classical apoptosis in general) in MRTF-mediated cell death might not be central. Alternatively, unidentified caspase-independent mechanisms could play a primary role here (see Discussion). In summary, over-expression of active, but not full length MRTF-A could be directly linked to the activation of classical markers of apoptosis. This activation, however, occurs on a relatively minor scale and unlikely to be solely responsible for the extensive cell death observed in the experiments.

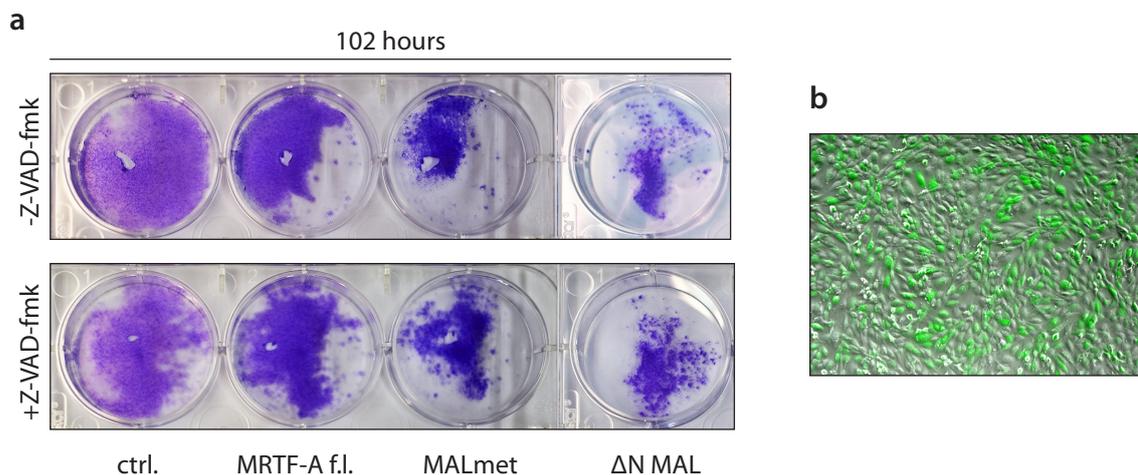

Figure IV-12: *Inhibition of caspases following MRTF-A over-expression.* **a.** NIH 3T3 cells were retrovirally infected with the indicated constructs and 20 μ M Z-VAD-fmk was added at time point 0 hours. Fresh caspase inhibitor was re-added every 12 hours for a total of 102 hours. Afterwards cells were fixed with 4% PFA and stained with crystal violet. **b.** Infection efficiency of pLPCX-eGFP vector 36 hours post-infection. Overlay of phase contrast and eGFP fluorescence. 10x magnification. >90% of cells are infected.

MRTF-A regulates expression of pro-apoptotic proteins Bok and Noxa.

IV.3.1. MRTF-A is sufficient and required for Bok and Noxa transcription

Having observed a strong anti-proliferative effect of MRTF-A on NIH 3T3 cells, it was intriguing to discover that the microarray screen for G-actin-regulated genes described in Section IV.1.1, have identified several putative SRF-MRTF targets with the known function in apoptosis execution. Among them, Pmaip/Noxa and Bok were found to be up-regulated by cytochalasin D (6.04- and 2.92-fold, respectively). This activation was partially blocked by pre-treatment with latrunculin B (to 1.26- and 2.38-fold respectively) (Table IV-1). We hypothesized that MRTF-A-dependent transcription of Bok and Noxa plays a role in the anti-proliferative effect seen in over-expression studies and potentially contributes to the apoptosis induced by other stimuli. Therefore, initial microarray validation and promoter characterization studies were done by Arnaud Descot, and I joined this project with the goal to investigate the role of MRTFs in the regulation of Bok and Noxa in more detail.

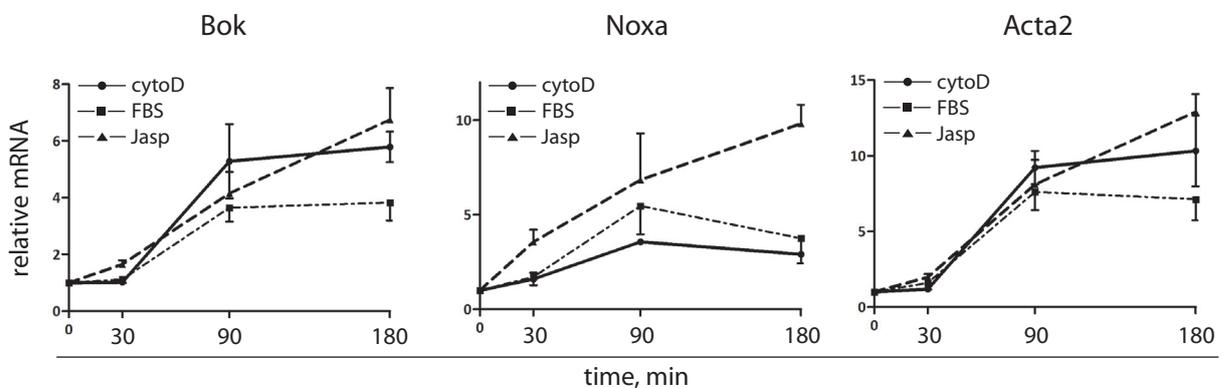

Figure IV-13: Bok and Noxa mRNA temporal dynamics. NIH 3T3 cells were treated with 2 μ M cytochalasin D (CytoD), 15% FBS or 0.5 μ M jasplakinolide (Jasp) for indicated periods of time. mRNA levels were quantified using real-time PCR and normalised to Hprt housekeeping control. Acta2 is a known SRF-MRTF target and served as a positive control. $n=3$, bars - SEM.

First, I examined the temporal dynamics of the Bok and Noxa mRNA following stimulation of NIH 3T3 cells with cytochalasin D, fetal bovine serum and F-actin stabilizing agent jasplakinolide, which is also able to activate SRF-MRTF signaling (Sotiropoulos *et al.*, 1999; Miralles *et al.*, 2003). Both Bok and Noxa mRNA levels were up-regulated at time points later than 30 minutes of stimulation (Figure IV-13). Induction profile of the Bok mRNA was similar to the control gene, smooth muscle α -actin, which is a well-characterized SRF-MRTF target.

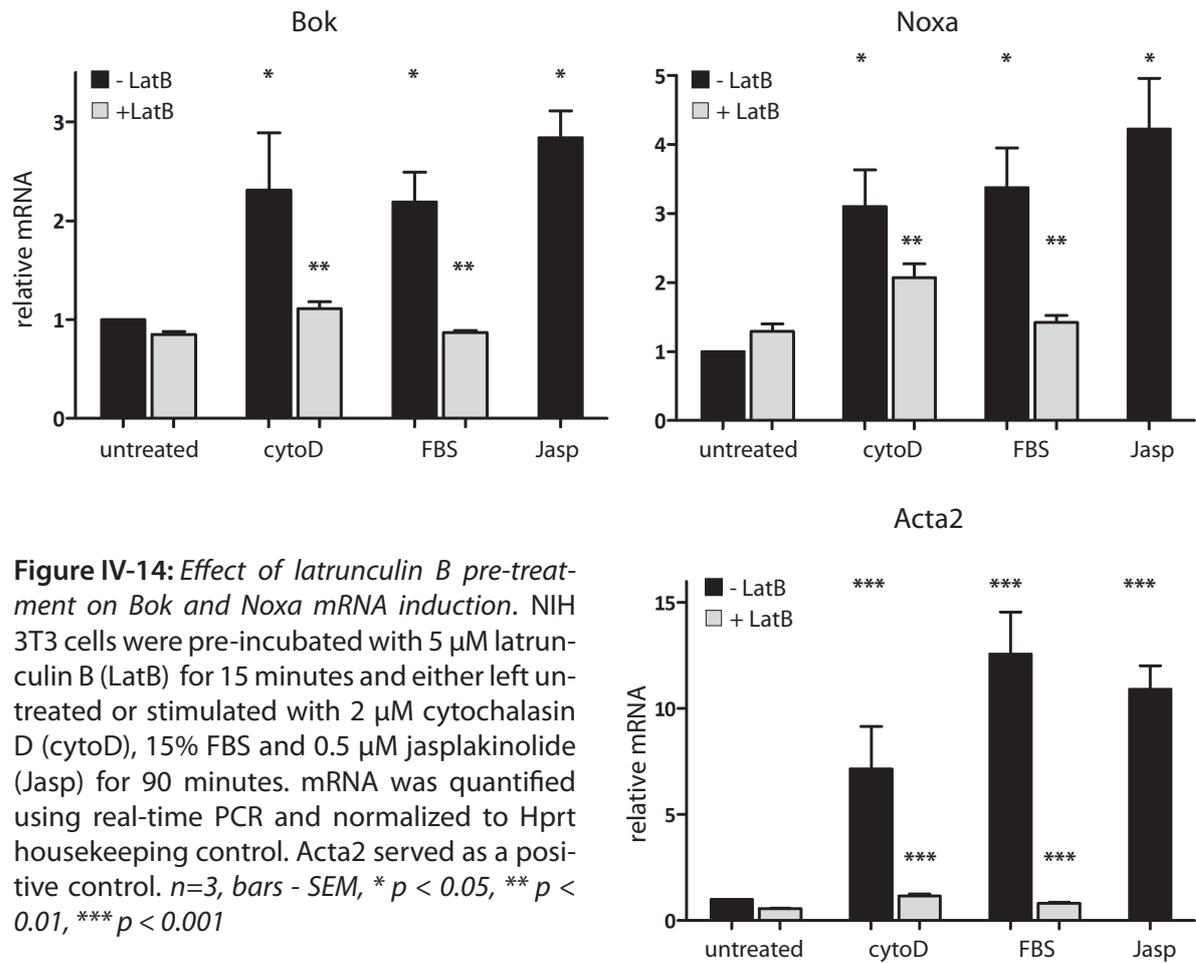

Figure IV-14: Effect of latrunculin B pre-treatment on Bok and Noxa mRNA induction. NIH 3T3 cells were pre-incubated with 5 μ M latrunculin B (LatB) for 15 minutes and either left untreated or stimulated with 2 μ M cytochalasin D (cytoD), 15% FBS and 0.5 μ M jasplakinolide (Jasp) for 90 minutes. mRNA was quantified using real-time PCR and normalized to Hprt housekeeping control. Acta2 served as a positive control. $n=3$, bars - SEM, * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Noxa mRNA, on the other hand, displayed more transient activation pattern, dropping to the resting levels after 90 minutes of stimulation. To reproduce the conditions from the microarray screen, I used the same stimuli alone or in combination with 15 minutes of latrunculin B pre-treatment. After 90 minutes of stimulation, latrunculin B pre-treatment has efficiently suppressed cytochalasin D and serum-induced mRNA up-regulation (Figure IV-14). Additionally, over-expression of constitutively active MRTF-A in NIH 3T3 cells led to approximately 10-fold increase in relative mRNA abundance of both Bok and Noxa (Shaposhnikov *et al.*, 2012).

Table IV-1: Bok and Noxa probe sets from the Affimetrix microarray (Descot *et al.*, 2009)

Probe set ID	Gene ID	Name	Induction		
			CytoD	CytoD+LatB	q-value
1417040_a_at	Bok	Bcl-2-related ovarian killer	2.92	1.26	0.00
1418203_at	Pmaip1	TPA-induced protein 1	6.04	2.38	1.14

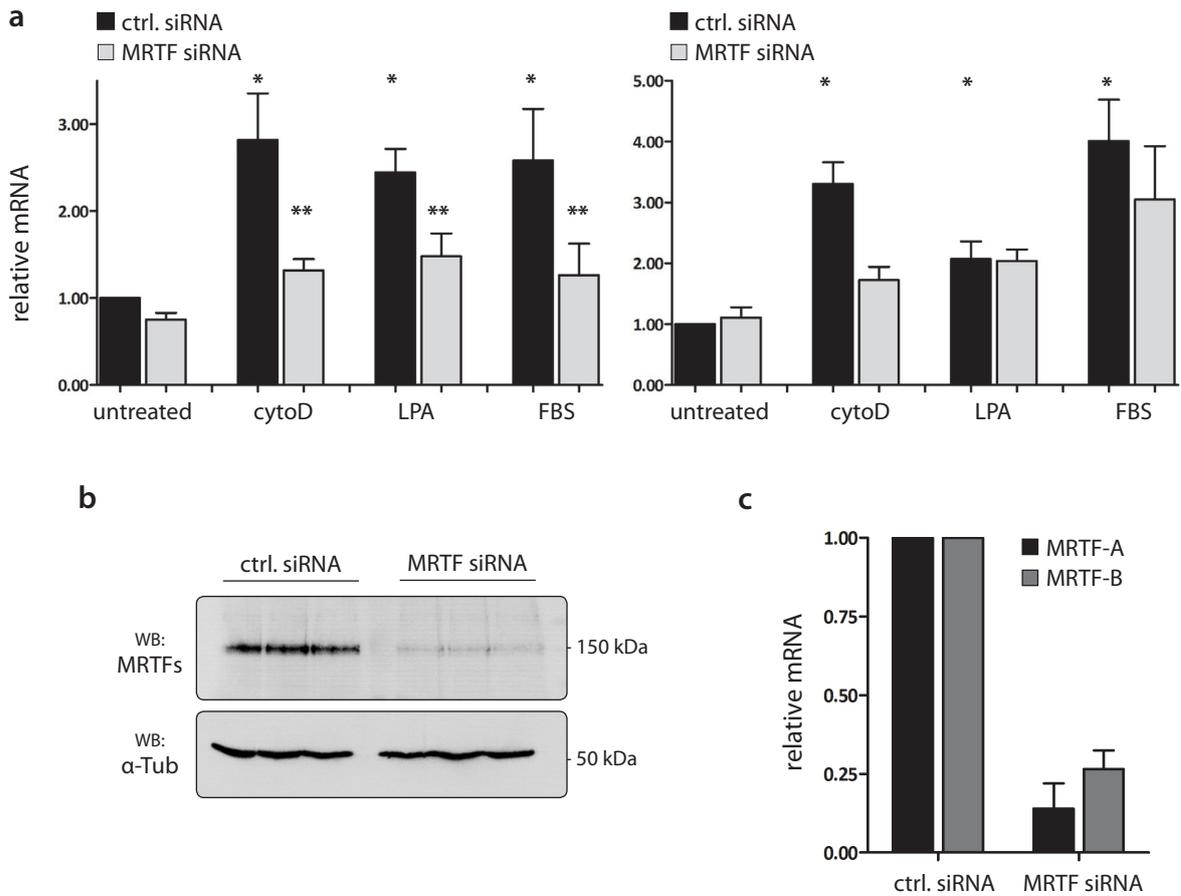

Figure IV-15: Stimulation-dependent accumulation of Bok/Noxa mRNA following MRTF knock-down. **a.** NIH 3T3 cells were transiently transfected with either control siRNA or siRNA against MRTFs. 12 hours post-transfection cells were serum starved for 24 hours and then either left untreated or stimulated with 2 μ M cytochalasin D, 10 μ M LPA or 15% FBS for 90 minutes. mRNA was quantified using real-time PCR and normalized to Hprt housekeeping control. $n=3$, bars - SEM, * $p<0.05$, ** $p<0.01$. **b.** Knockdown efficiency estimated by Western blotting and qPCR.

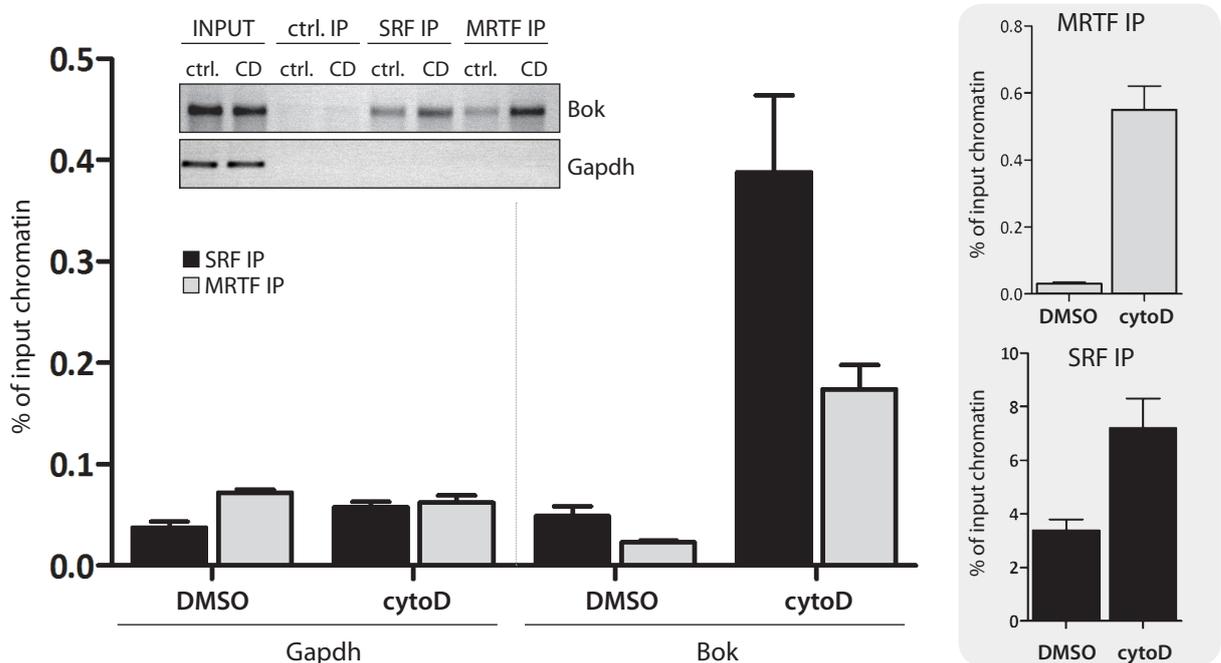

Figure IV-16: *Bok* chromatin immunoprecipitation. CarG-like element at position -99 in the proximal Bok promoter recruits SRF and MRTF-A/B after stimulation with 2 μ M cytochalasin D (30 minutes time point). Grey inset shows recruitment of SRF and MRTFs to a positive control promoter - Srf itself. $n=3$, bars - SEM.

Next I performed MRTF knockdown in the same cells to evaluate whether MRTFs are required for up-regulation of Bok and Noxa mRNA. In transient siRNA-mediated knockdown followed by stimulation with cytochalasin D, lysophosphatidic acid (LPA) and serum, Bok mRNA induction was severely impaired, while Noxa mRNA was affected less strongly (Figure IV-15A). In contrast, transient retroviral infections with shRNA of the same sequence have shown complete abrogation of induction for both genes (Shaposhnikov *et al.*, 2012). This discrepancy might be a result of varying transfection/knockdown efficiencies between two knockdown methods, although siRNA-mediated knockdown was acceptably efficient (Figure IV-15B). Together, this data provided evidence that Bok and Noxa genes could be directly regulated by SRF-MRTF signaling pathway.

To identify SRF-MRTF responsive element in the promoters of Bok and Noxa, *in silico* analysis of proximal promoter regions was performed by Arnaud Descot. Immediate promoter of the Noxa gene (-2000..+1) contains one CARG-like element carrying a single mismatch from the consensus CARG box. Additional consensus CARG box was identified in the first intron of the gene. Similarly to the results obtained for some other target genes (Pai-1, Fhl1), ChIP experiments failed to show any significant binding of SRF or MRTFs to these cis-regulatory elements. We conclude, therefore, that Noxa regulation via SRF-MRTF pathway is unlikely to occur via proximal promoter or the first intronic region. On the other hand, a single CARG-like element at position -99 in the immediate promoter of the Bok gene was solely responsible for the promoter activity in luciferase reporter assays (Shaposhnikov *et al.*, 2012). Using stimulation with cytochalasin D followed by chromatin immunoprecipitation, I was able to show an inducible recruitment of both SRF and MRTFs to this CARG box (Figure IV-16). Similarly to the Plakophilin 2 promoter, SRF was not constitutively bound to the Bok promoter, like in classical SRF targets (*acta2*, *Srf*), but was inducibly recruited to the CARG box upon stimulation.

IV.3.2. The role of p53 in Bok and Noxa transcriptional regulation.

To date both Bok and Noxa genes have been thought as primarily regulated by p53 transcriptional factor. Direct p53 binding to the Noxa promoter has been shown previously (Oda *et al.*, 2000) and Noxa-deficient mouse embryonic fibroblasts were insensitive to p53-

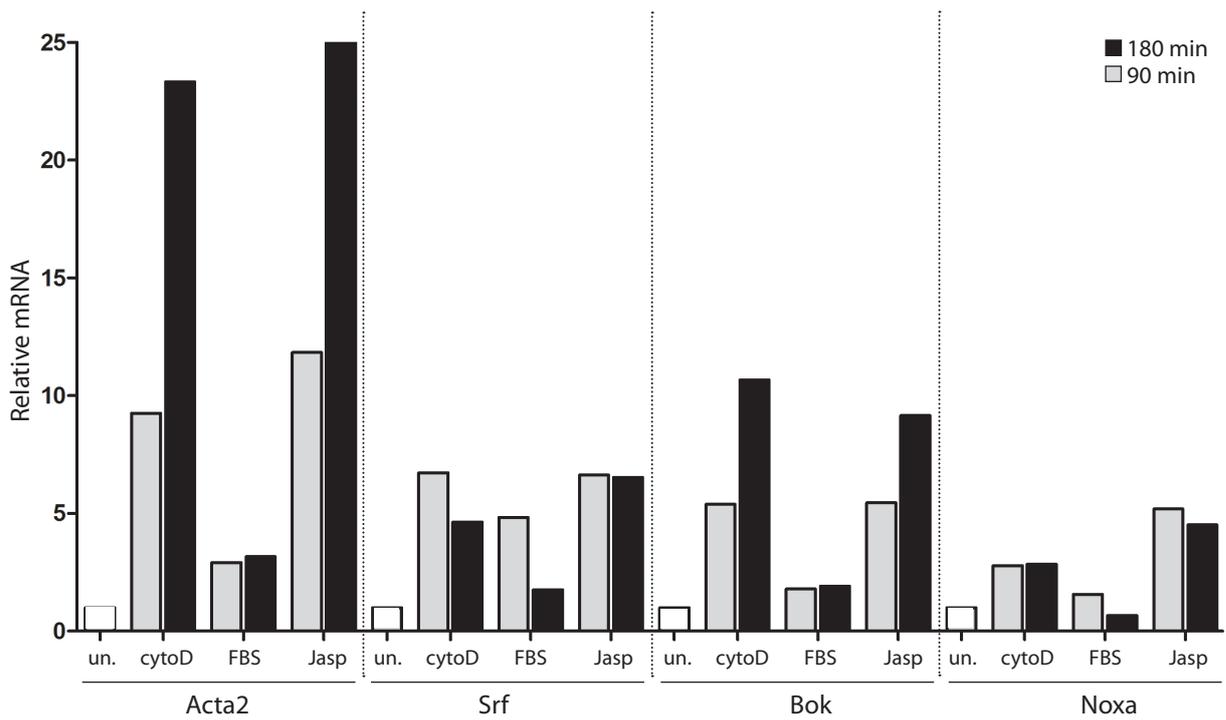

Figure IV-17: Stimulation-dependent induction of Bok and Noxa in wild type MEFs. MEF^{wt} were serum starved for 24 hours and either left untreated (un.) or stimulated with 2 μM cytochalasin D (CytoD), 15% FBS or 0.5 μM jaspalakinolide (Jasp) for 90 and 180 minutes. mRNA was quantified using real-time PCR and normalized to Hprt housekeeping control. *n*=1.

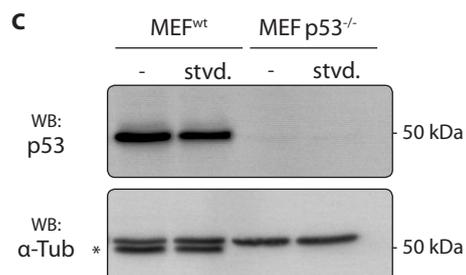

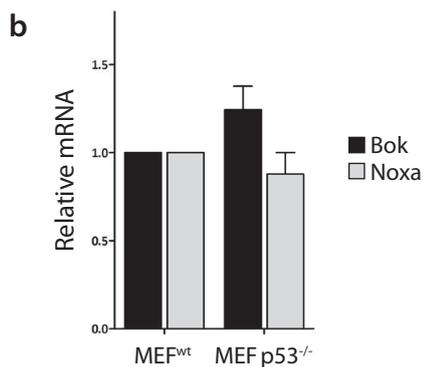

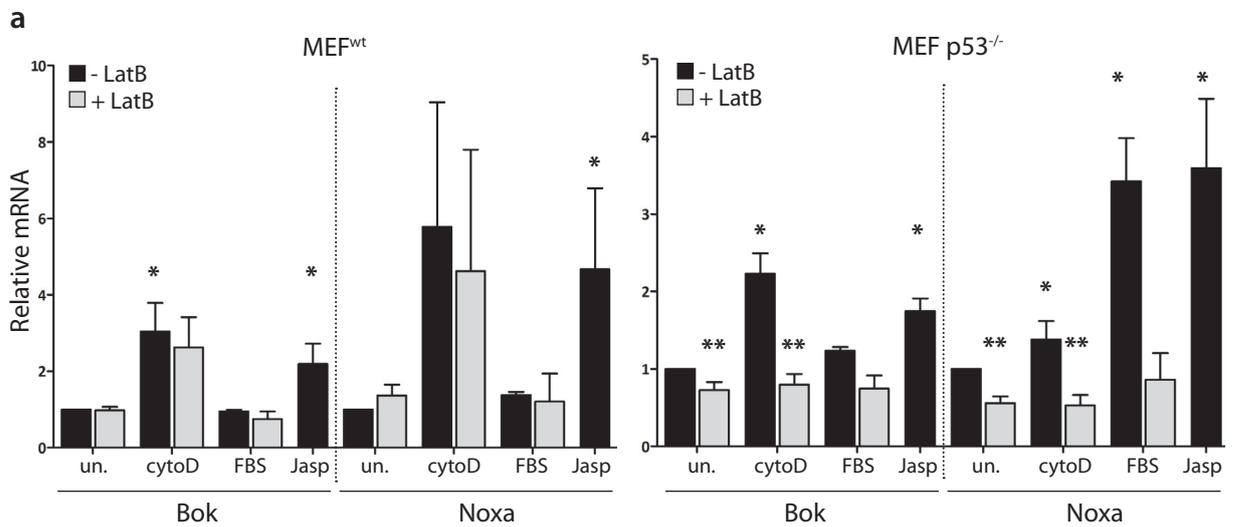

Figure IV-18: Stimulus-dependent induction of *Bok* and *Noxa* mRNA in *p53*-null MEFs. **a.** Either wild type MEFs (MEF^{wt}) or *p53*-null MEFs (*p53*^{-/-}) were starved for 24 hours and pre-incubated with 5 μ M latrunculin B (LatB) for 15 minutes, then were either left untreated or stimulated with 2 μ M cytochalasin D (cytoD), 15% FBS and 0.5 μ M jasplakinolide (Jasp) for 90 minutes. mRNA was quantified using real-time PCR and normalized to *Hprt* housekeeping control. $n=3$, bars - SEM, * $p < 0.05$, ** $p < 0.01$. **b.** Alterations of basal *Bok* and *Noxa* mRNA levels in wild type versus *p53*^{-/-} MEFs, $n=3$. **c.** Western blot showing the absence of *p53* protein in *p53*-null MEFs. Asterisk indicates residual *p53* signal after membrane stripping. (-) cells grown in 10% FBS, stvd. - serum starvation for 24 hours (0.5% FBS).

mediated apoptosis induced by etoposide (Villunger *et al.*, 2003). *Bok* expression was strongly suggested to be *p53*-dependent (Yakovlev *et al.*, 2004), although there is still no direct evidence of direct binding of *p53* to the promoter. In order to dissect the influence of the *p53* on SRF-MRTF-mediated *Bok* and *Noxa* regulation, I first tested the induction of both genes in immortalized wild-type mouse embryonic fibroblasts (MEF^{wt}). Employing stimulations with serum, cytochalasin D and jasplakinolide, I established that both genes were induced, although serum-induced up-regulation was generally weak (Figure IV-17). Noteworthy, time-course analysis revealed two distinct patterns of mRNA induction - while *Bok* mRNA was still accumulating at 180 minutes of stimulation, similarly to the *Acta2* positive control gene, *Noxa* mRNA levels were stabilized at 90 minutes of stimulation and were not up-regulated further, reminiscent of another positive control gene - *Srf*. With this knowledge in hand, I compared *Bok* and *Noxa* mRNA induction between wild-type MEFs and *p53*-deficient MEFs, derived from *p53* knockout mouse. Despite the fact that *p53* protein was effectively absent from *p53*^{-/-} MEFs, the basal levels of *Bok* and *Noxa* mRNA remained essentially unchanged, although *Bok* might have been slightly up-regulated (Figure IV-18B-C). SRF-MRTF pathway-activating stimuli cytochalasin D, FCS and jasplakinolide were able to up-regulate both genes in the absence of *p53*, while pre-treatment with latrunculin B blocked the induction (Figure IV-18A). Of note, in *p53*^{-/-} MEFs, latrunculin B alone had significantly impaired not only induced expression, but also basal levels of *Bok* and *Noxa* mRNA. On the other hand, while latrunculin B did not significantly influence basal expression of the genes in wild-type settings, its effect on the mRNA induction was also minimal. In summary, this data provided evidence for *p53*-independent regulation of *Bok* and *Noxa* by actin cytoskeleton-

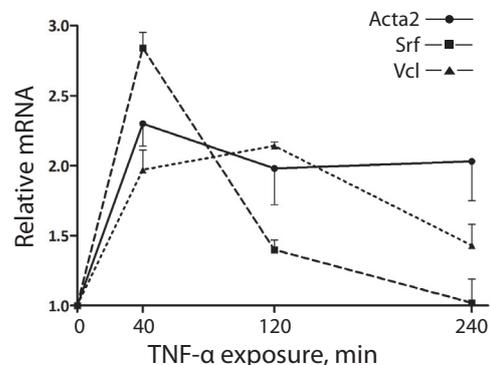

Figure IV-19: Induction of known SRF-MRTF target mRNA upon TNF- α treatment. NIH 3T3 cells were treated with 10 ng/mL TNF- α for indicated periods of time. mRNA quantified using real-time PCR and normalized to *Hprt*. $n=3$, bars - SEM

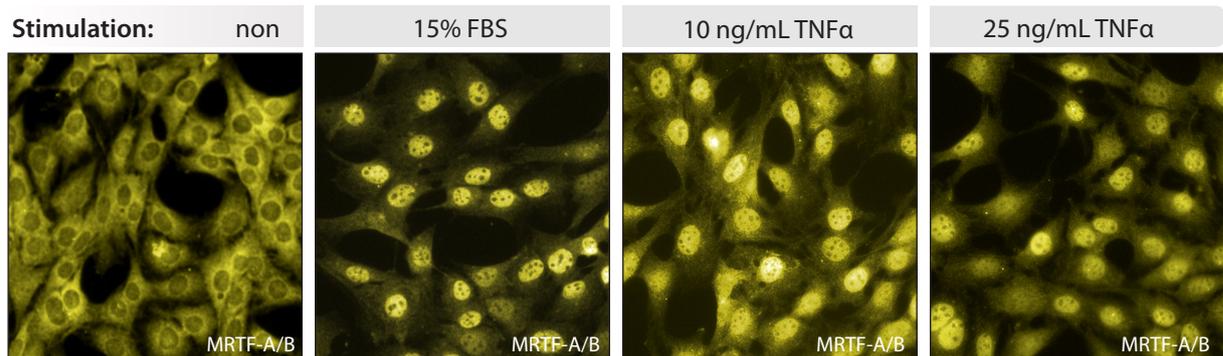

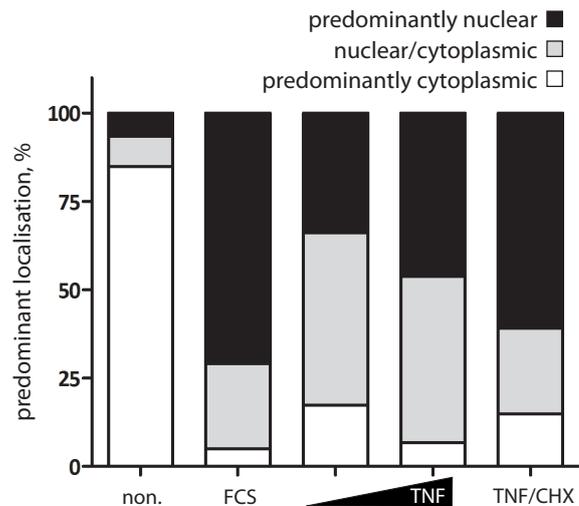

Figure IV-20: Nuclear translocation of endogenous MRTF-A/B upon stimulation with TNF- α . NIH 3T3 cells were serum starved for 24 hours and treated with 15% FBS (positive control) and increasing concentrations of TNF- α (10 ng/mL also in combination with 10 μ g/mL cycloheximide) for 30 minutes. Afterwards cells were fixed and stained with anti-MRTF antibody and secondary Alexa 546-conjugated antibody. On the left are quantified results ($n=100$ cells). Representative experiment.

targeting agents and SRF-MRTF pathway.

IV.3.3. Are SRF-MRTFs required for apoptosis induction?

Having identified two pro-apoptotic targets of SRF-MRTF pathway we were interested to see whether MRTF activity is involved in induction of treatment-induced apoptosis. Previously, Arnaud Descot looked at the activity of SRF-MRTF pathway in TNF α - and staurosporine-induced apoptosis using luciferase reporter assays. Using NIH 3T3 fibroblasts, he found that the activity of the pathway is, indeed, induced by these agents in a dose-dependent manner and efficiently blocked by pre-treatment with latrunculin B (Shaposhnikov *et al.*, 2012). Using TNF α as an activator of extrinsic apoptotic event, I analyzed whether it is able to induce some of the classical SRF-MRTF target genes. Upon stimulation, *Acta2*, *Srf* and *Vcl* genes were quickly up-regulated in NIH 3T3 cells (Figure IV-19). mRNA levels of *Srf* and *Vcl* have dropped to the resting levels after 120 minutes, while *Acta2* expression remained elevated. This induction kinetics is similar to the one observed in cytochalasin D or serum-stimulated cells, although on a smaller absolute scale. The fact that elevated mRNA levels are detected at 40 minutes of TNF α stimulation points to the fact that MRTF activation is a direct TNF-mediated event, rather than a result of secondary indirect signaling.

Supporting the mRNA induction data, TNF α treatment efficiently induced dose-dependent nuclear accumulation of MRTFs (Figure IV-20). Moreover, this accumulation was not affected by protein synthesis inhibitor cycloheximide, confirming the notion that MRTF activation is an early event, rather than a consequence of late TNF α signaling. MRTFs accumulate in the nucleus as a result of dissociation from inhibitory complex with G-actin in cytoplasm, but their localization in the nucleus does not strictly correlate with activation of transcription since they can be repressed via binding to the nuclear G-actin (Vartiainen *et al.*, 2007). However, translocation data combined with the target gene induction allows suggesting that TNF α induces SRF-MRTF pathway. Unexpectedly, TNF α stimulation of NIH 3T3 and MEF cells failed to up-regulate either Bok or Noxa genes, while cytochalasin D led to a robust induction of the transcripts (data not shown). This strongly points to the stimulus-specific regulation of Bok and Noxa and puts their importance in extrinsic pathway of apoptosis under question mark.

Additionally, DNA-damaging agents, etoposide and doxorubicin were not active in the luciferase reporter assays for SRF-MRTF activity and failed to up-regulate Bok expression at up to 180 minutes of stimulation (data not shown). On the contrary, Noxa mRNA was strongly induced by these agents in both NIH 3T3 and wild-type MEF cells. However, this induction was completely abrogated in p53-null MEF line, arguing that DNA damage-induced apoptotic signaling uses exclusively p53 for regulation of Noxa, but not Bok. In summary, these experiments present evidence for SRF-MRTF involvement in the transcriptional regulation of pro-apoptotic genes Bok and Noxa. Although SRF-MRTF pathway appears to be activated upon certain apoptotic stimuli, e.g. TNF α and staurosporine, it does not activate the transcription of either Bok or Noxa and its role in the apoptotic signaling is not yet clear. DNA damage-induced apoptosis (after etoposide and doxorubicin treatments) does not seem to activate SRF-MRTF pathway or up-regulate Bok transcript. It is, however, accompanied by Noxa up-regulation, which appears to be strictly p53-dependent.

MRTFs and their role in the cell cycle regulation

IV.4.1. MRTF-A/B knockdown leads to increase in S and G2/M populations in the absence of growth factors.

Marked anti-proliferative effect observed upon the overexpression of the active forms of MRTF-A has also been described for a founding member of the family, myocardin. In one study, myocardin overexpression was found to positively correlate with the up-regulation of a cyclin-CDK inhibitor p21^{Waf1} and a consequent G1-S arrest (Kimura *et al.*, 2010). Contradicting this data, another study has found no effect on p21^{Waf1}, but found down-regulation of a number of cell cycle regulatory proteins (CDK2, CDK1, S6K) and *c-myc* to be responsible for G2-M arrest and accumulation of polyploid cells (Tang *et al.*, 2008). Our analysis of anti-proliferative effects of MRTF-A overexpression did not involve any cell cycle regulators, however, during transient, siRNA-mediated, MRTF-A/B knockdown we observed an interesting phenomenon: when MRTF-A/B depleted NIH 3T3 cells were deprived from growth factors by serum starvation, they still displayed a significant amount of cells in the S and G2 phases of cell cycle. Such an effect would be consistent with the idea that if active MRTF-A conveys anti-proliferative response, depleting cells from MRTFs would give them proliferative advantage.

In order to investigate the role of MRTF depletion in proliferation and cell cycle regulation of NIH 3T3 fibroblasts, I used siRNA sequence targeting both MRTF isoforms: A and B (Medjikane *et al.*, 2009). Quantitative PCR has shown more than 84% decrease in MRTF-A mRNA and more than 70% decrease in MRTF-B mRNA 24 hours post-transfection (Figure IV-21B). Western blotting has confirmed almost

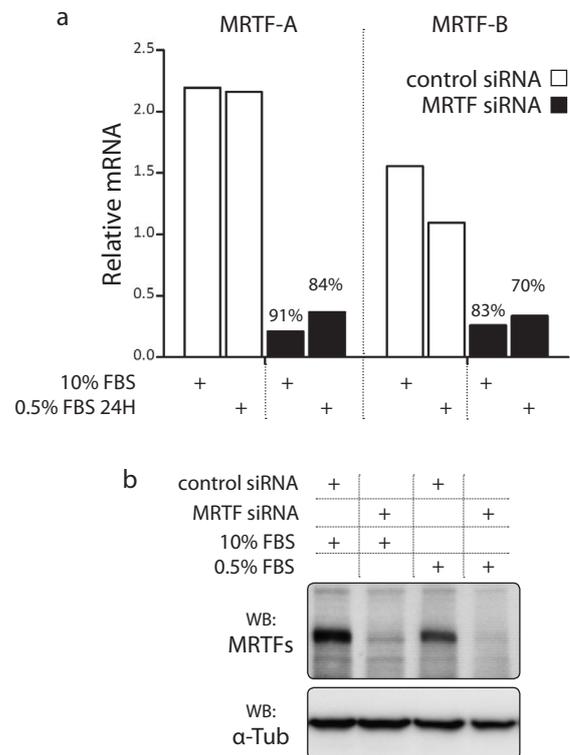

Figure IV-21: Efficiency of a transient siRNA-mediated knockdown of MRTF-A/B. **a.** Real-time PCR showing MRTF-A and -B mRNA levels 36 hours post-transfection in full medium or including 24 hours of serum starvation. Normalized to Hprt, $n=1$. **b.** Western blot showing MRTF-A/B protein levels on the same time scale as in **a**. Representative experiments.

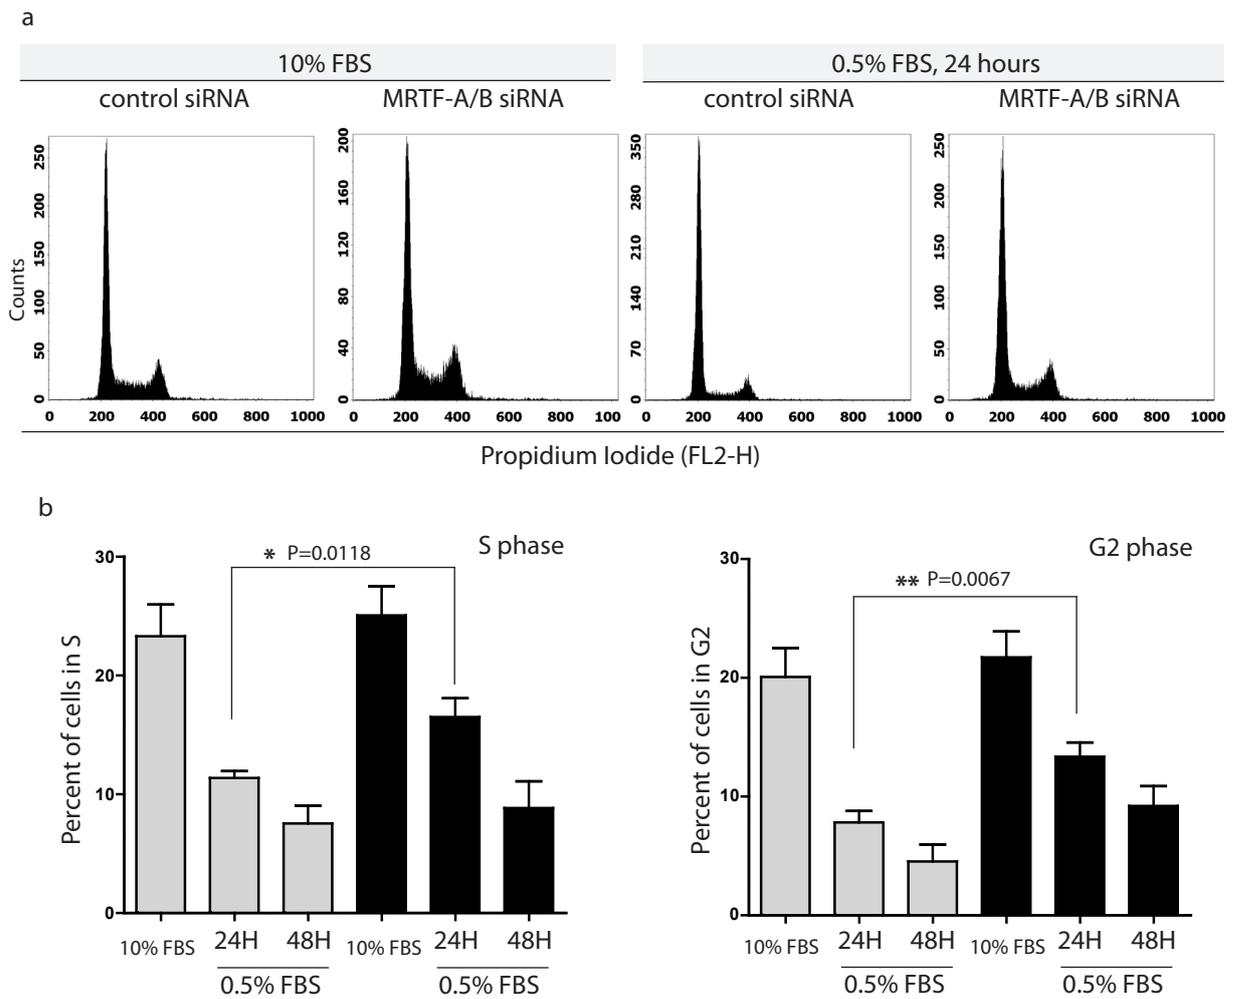

Figure IV-22: Increased S-G2 populations following transient knockdown of MRTFs. NIH 3T3 cells were transfected with either control siRNA or siRNA against MRTFs and grown in 10% FBS- or 0.5% FBS-containing medium for 24 hours. Cell cycle phase distribution was assessed by propidium iodide staining and FACS analysis. 10000 cells were collected per sample. **a.** representative histograms of cell cycle distribution after gating on single cell population. **b.** quantification of S and G2 phase populations using Dean-Jet-Fox algorithm. $n \geq 3$, bars - SEM, statistical significance indicated on graphs

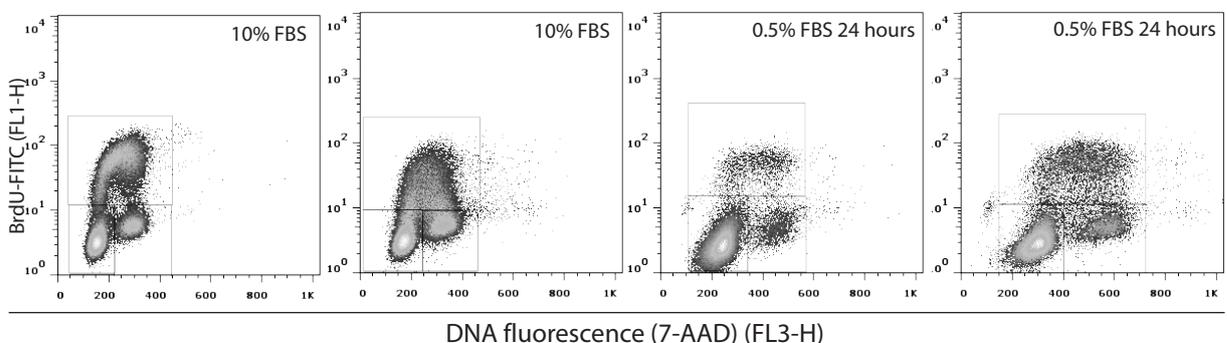

Figure IV-23: Increased S population following MRTF knockdown is BrdU-positive. NIH 3T3 cells were grown as in Fig. II-22, pulse-labeled with BrdU for 20 minutes and stained with FITC-conjugated anti-BrdU antibody and 7-AAD. Analysed by FACS. 50000 cells collected per sample. Representative scatter plots after gating out debris and cell clumps. Gates on G1, S and G2/M populations are shown. $n=3$

complete depletion of MRTF proteins at the same time point (Figure IV-21A). Propidium iodide staining of cell cycle distribution has shown that NIH 3T3 cells asynchronously growing in the full medium (10% fetal bovine serum (FBS)) did not display any significant differences

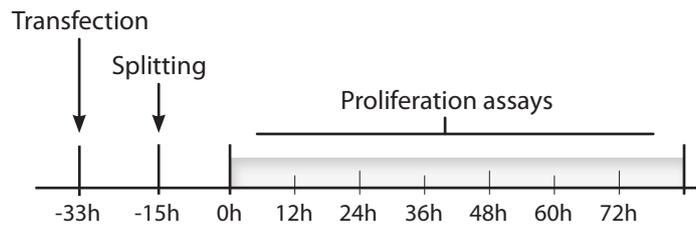

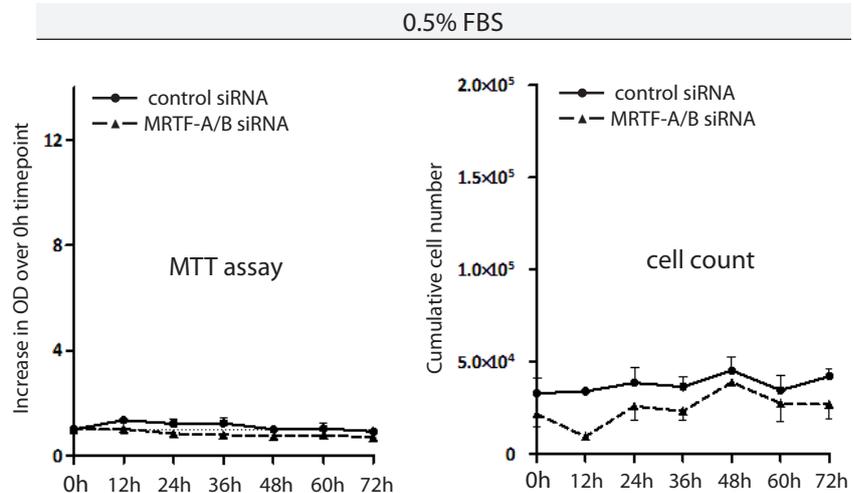

Figure IV-24: Outline of proliferation assay setup. MTT assay and cell counting were performed in parallel.

between control siRNA and MRTF knockdown. However, when serum starved using 0.5% FBS in the culture medium, cells depleted from MRTFs had considerably more cells in S and G2 phases of the cell cycle (Figure IV-22). To clarify whether the increased S phase came from the slippage through G1-S checkpoint or is a result of an arrest during S phase, I pulse-labeled transfected cells with BrdU to detect newly synthesized DNA. Consistent with the experiments above, serum-starved, MRTF-depleted cells had significantly increased S and G2 populations (Figure IV-23). Cells in the S phase were clearly BrdU-positive, indicating that

Figure IV-25: Growth curves in serum-starved conditions following MRTF knock-down. NIH 3T3 cells were grown in medium containing 0.5% FBS. Growth curves generated according to Figure II-24. $n=3$, bars - SEM

in the absence of growth factors, MRTF knockdown confers the ability of cells to escape G1-S arrest. On the other hand, cells grown in presence of 10% serum had very similar cell cycle distributions.

IV.4.2. MRTF-A/B knockdown impairs proliferation of NIH 3T3 fibroblasts.

To inspect whether this G1-S slippage allows MRTF-depleted cells to proliferate in the absence of growth factors, I constructed the growth curves of the cells with and with-

out knockdown using 2 different proliferation assays (Figure IV-24), which showed similar results. In MTT assay as well as in direct cell counting, MRTF-depleted cells failed to proliferate in 0.5% FCS (Figure IV-25), demonstrating that the increase in S and G2 populations is not followed by cell divi-

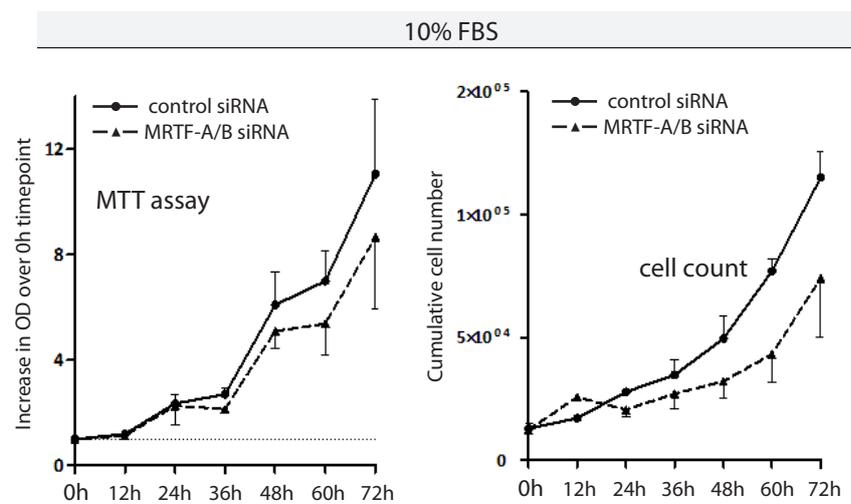

Figure IV-26: Growth curves in 10% FBS following MRTF knockdown. NIH 3T3 cells were grown in full medium containing 10% FBS. Growth curves generated according to Figure II-24. $n=3$, bars - SEM

sion and increase in cell numbers. Thus, the cells that aberrantly entered S phase in the absence of serum are likely to be arrested and destined for apoptosis. Interestingly, in cells grown in 10% serum, MRTF knockdown led to reproducible delay in proliferation rate (Figure IV-26), which could not be accounted for by increase in apoptosis as determined by annexin V staining (not shown). This data prompts to suggest that MRTF knockdown, instead of giving cells proliferative advantage, also confers anti-proliferative effect, although on a far lesser scale than active MRTF-A over-expression.

IV.4.3. MRTF-A/B knockdown changes the lengths of cell cycle phases.

In order to gain a deeper understanding of MRTF depletion effects on the cell cycle, I created two stable, NIH 3T3-based, cell lines that allowed for monitoring cell cycle progression in real time. First cell line expressed histone H2B-GFP fusion protein, conferring green nuclear fluorescence to the cells throughout cell cycle. Second cell line contained so-called FUCCI markers (Sakaue-Savano *et al.*, 2008). Both marker proteins were expressed from a single vector with the help of IRES2 sequence (Figure IV-27), which represents a slight modification of the original system where markers are encoded on separate plasmids. FUCCI-expressing cells display orange nuclear fluorescence during G1 phase due to accumulation of the first marker protein – Cdt1(30-120)-mKO2 (amino acids 30-120 of a DNA

Figure IV-27: Scheme of pGIC vector, encoding FUCCI markers.

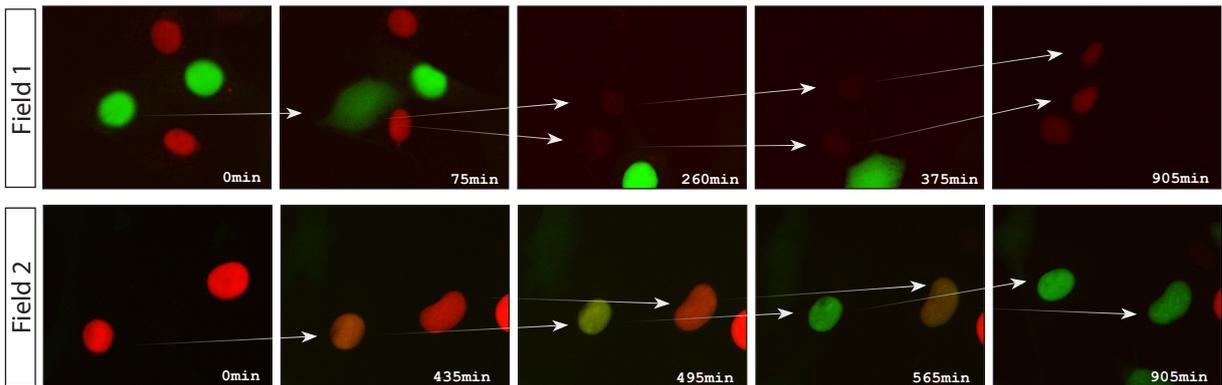

Figure IV-28: Live cell imaging of NIH 3T3 cells stably expressing Fucci markers. Field 1 follows two cells in G2 phase (t=0, t=260) undergo nuclear envelope breakdown (t=75, t=375) followed by mitosis. Daughter cells develop red fluorescence. In field 2 two cells in G1 (t=0) undergo progression to S phase accompanied by the change in fluorescent color from red to green

replication factor Cdt1 fused to monomeric Kusabira Orange 2 protein). At the onset of S phase it is degraded by the SCF^{Skp2} E3 ligase complex, resulting in the disappearance of red fluorescence. At the same time, very early in the S phase, second marker – Geminin (1-110)-mAG (amino acids 1-110 of DNA replicator inhibitor Geminin fused to monomeric Azami Green protein) becomes de-repressed. Its accumulation gives cells green nuclear fluores-

Figure IV-29: Comparison of knockdown efficiency between non-labeled MRTF siRNA and MRTF siRNA labeled with Cy5 on 3' end of the sense strand. NIH 3T3 cells transfected with indicated siRNAs were assayed 36 hours post-transfection. Cy5 label does not affect siRNA's potency.

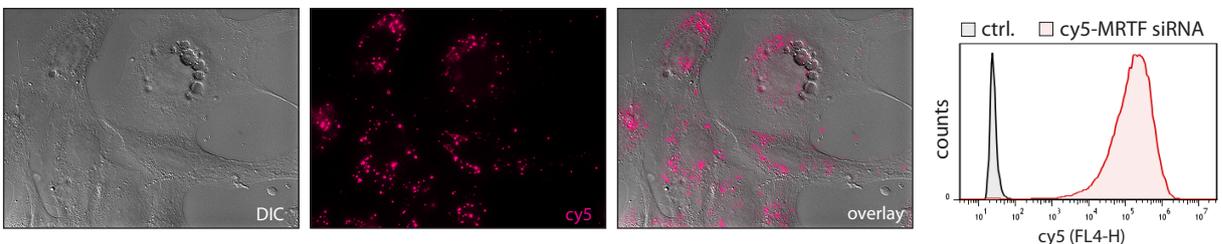

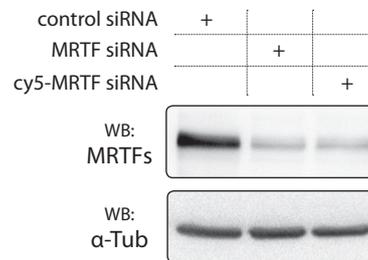

Figure IV-30: siRNA transfection efficiency. NIH 3T3 cells were transfected with cy5-labeled anti-MRTF siRNA and 24 hours later efficiency of transfection was estimated using microscopy and FACS analysis. Micrographs showing fixed cells exposed in DIC and Cy5 channels at 20x magnification On the right, FACS analysis showing histograms of non-labeled siRNA (ctrl.) and cy5-labeled anti-MRTF siRNA. Transfection efficiency is >98%.

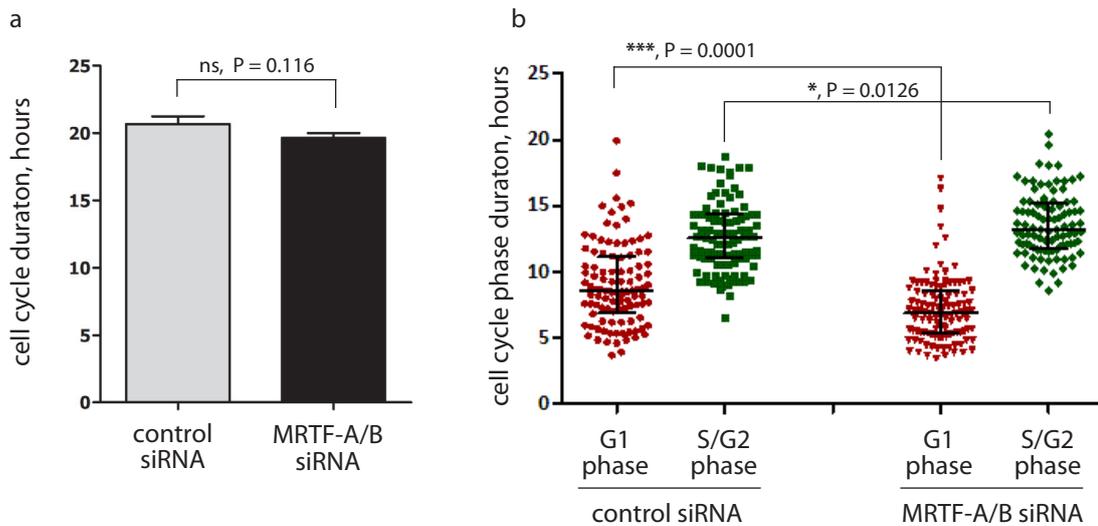

Figure IV-31: Quantification of live cell imaging of FUCCI-expressing NIH 3T3 cells. **a.** Total time between two cell division is not significantly changed upon MRTF knockdown. $n=54$ for control siRNA, $n=62$ for MRTF siRNA. bars -SEM. **b.** Duration of individual cell cycle phases is changed following MRTF knockdown. $n > 100$ cells for each sample. Median and interquartile distance are indicated.

cence which persists through S, G2 and most of the M phase. During late mitosis, Geminin(1-110)-mAG is degraded by the APC^{Cdh1} E3 ligase complex, which remains active until the end of G1 phase. An example of cell cycle-dependent shifts in fluorescent color of the cells is presented in Figure IV-28 for stably transfected NIH 3T3 cells. I used these cells to monitor the duration of the cell cycle changes upon transient MRTF knockdown. In order to monitor the siRNA transfection efficiency and to focus only on siRNA-positive cells, all live imaging experiments have been performed using cy5-labeled siRNA against MRTFs. Prior to undertaking imaging experiments I have shown that the addition of fluorescent dye to the 5'-end of siRNA did not influence its ability to knock down MRTFs (Figure IV-29). Moreover, fluorescent imaging of transfected cells have clearly shown that the efficiency of siRNA delivery is close to 100% (Figure IV-30), giving me confidence to count every analyzed cell as siRNA-positive. As revealed by three independent live imaging experiments, the total duration of cell cycle between control siRNA and MRTF-targeting siRNA remained essentially unchanged (Figure IV-31A). Quantification of the duration of individual cell cycle phases has unveiled that

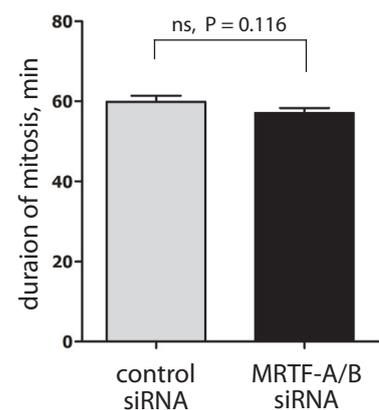

Figure IV-32: Duration of mitosis upon MRTF knock-down. NIH3T3-H2B-GFP cells transfected with the indicated siRNAs. $n \geq 35$ cells for each sample, bars -SEM

Figure IV-33: Downregulation of *p18INK4c* and *p19INK4d* upon MRTF knockdown. RNA was prepared 36 hours post-transfection (36h in 10% FBS or 12h + 24h in 0.5% FBS). mRNA was quantified using real-time PCR and normalized to Hprt. *n*=3, bars - SEM. Statistical significance indicated on graphs.

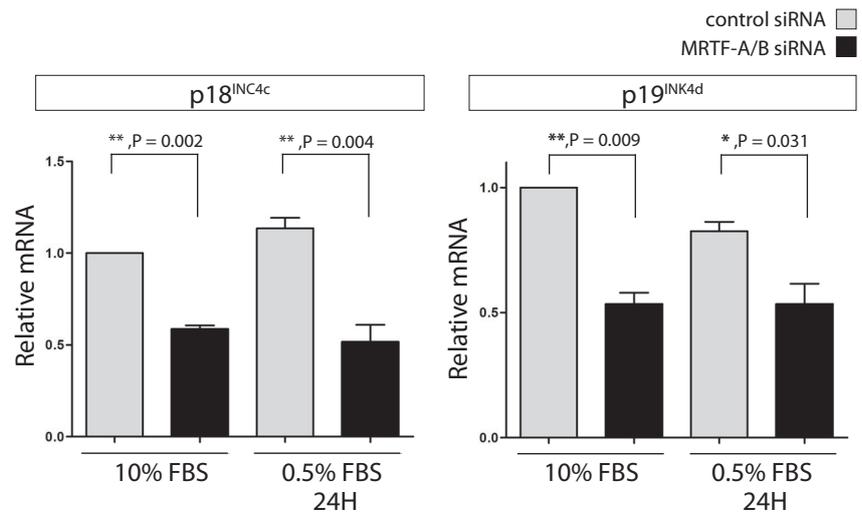

Figure IV-34: Changes in mRNA of CIP/KIP family members upon MRTF knockdown. RNA was prepared 36 hours post-transfection (36h in 10% FBS or 12h + 24h in 0.5% FBS). mRNA was quantified using real-time PCR and normalized to Hprt. *n*=3, bars - SEM. Statistical significance indicated on graphs.

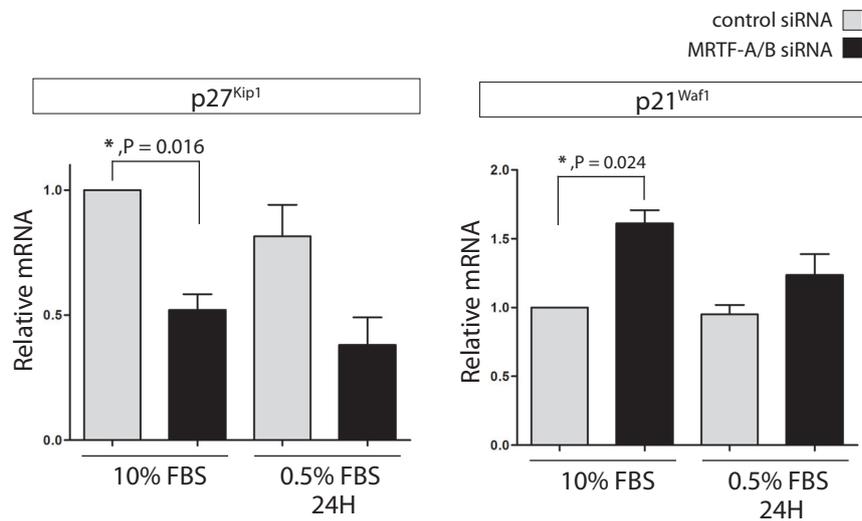

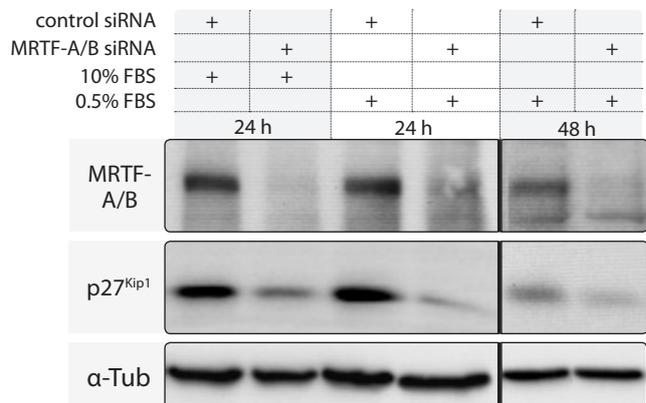

Figure IV-35: Downregulation of *p27^{Kip1}* following MRTF knockdown. 12 hours post-transfection NIH 3T3 cells were either incubated in full medium (10% FBS) for 24 hours or in serum-depleted medium (0.5% FBS) for 24 and 48 hours. Knockdown efficiency assessed by blotting against MRTF-A/B protein. Representative western blot pictures from 3 independent experiments.

MRTF knockdown leads to significant shortening of the G1 phase, from 9.028 ± 0.3 (SEM, *n*=104) hours in control siRNA to 7.154 ± 0.24 (SEM, *n*=112) hours in targeting siRNA. S-G2 phase, on the other hand, was slightly, but significantly longer (12.65 ± 0.26 hours for control versus 13.54 ± 0.24 for MRTF knockdown) (Figure IV-31B). Duration of the mitosis was com-

pared between two conditions with the help of H2B-GFP expressing NIH 3T3 cells. I calculated the time cells required from the nuclear envelope breakdown to complete cytokinesis and found no significant differences between control transfection and MRTF knockdown (Figure IV-32).

IV.4.4. MRTF-A/B knockdown influences cell cycle protein levels.

To link the observed changes in cell cycle phase durations to the molecular events I examined the effects of MRTF depletion on some key cell cycle regulators. Members of the cyclin-CDK inhibitor family INK4 play an important role in progression through G1-S checkpoint (Besson et al., 2008). Three out of five existing family members – p15^{INK4b}, p16^{INK4a}, p19^{ARF} – could not be detected in NIH 3T3 cells (data not shown), while other two – p18^{INK4c} and p19^{INK4d} – were significantly down-regulated on mRNA level following MRTF knockdown (Figure IV-33). Members of the second family of cyclin-CDK inhibitors, CIP/KIP proteins p21^{Waf1} and p27^{Kip1} were differentially affected by the knockdown. While p27^{Kip1} was down-regulated, p21^{Waf1}

Figure IV-37: Changes in Rb protein upon MRTF knockdown. NIH 3T3 cells were transfected with the indicated siRNAs (control and anti-MRTF) for 12 hours and then incubated either in full medium (10% FBS) for 24 hours or in serum-depleted medium (0.5% FBS) for 24 and 48 hours. For MRTF knockdown efficiency see Figure II-35. Representative western blot pictures from three independent experiments.

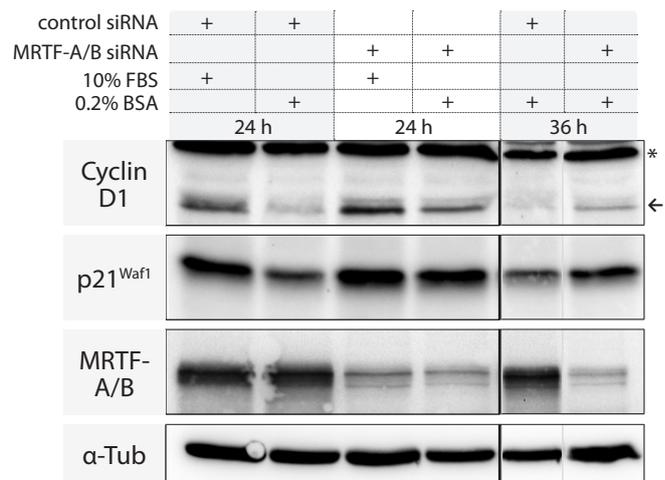

Figure IV-36: Changes in p21^{Waf1} and cyclin D1 levels following MRTF knockdown. NIH 3T3 cells were transfected with siRNAs (control or anti-MRTF) for 12 hours and incubated in either full medium (10% FBS) for 24 hours or in medium lacking FBS (0.2% BSA) for 24 and 36 hours. Asterisk indicates non-specific signal. Representative western blot pictures from three independent experiments.

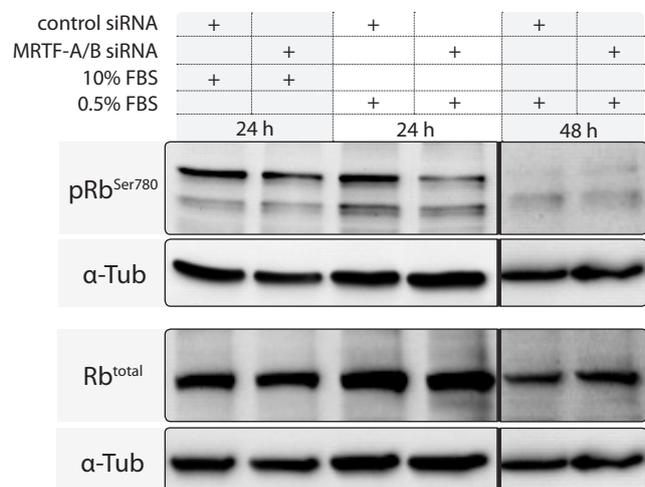

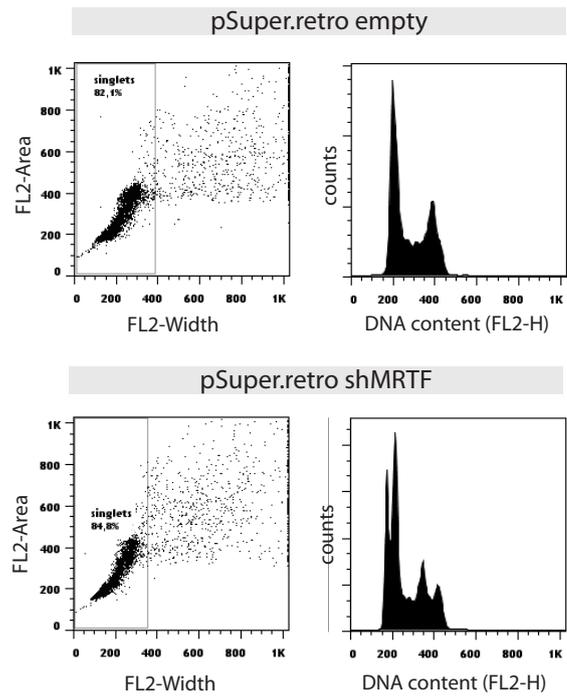

Figure IV-38: Aneuploidy in stable MRTF knock-down. NIH 3T3 cells transfected with either empty pSuper.retro.puro plasmid or pSuper.retro.puro-shMRTF and selected with puromycin for 3 weeks. FACS analysis of propidium iodide stained cells. 10000 cells collected per sample. On the right - scatter plot used to gate out cell clumps, singlet population is indicated.

displayed elevated mRNA levels following siRNA treatment (Figure IV-34). Of note, these effects were similar in both growth conditions (10% serum versus 0.5% serum). Consistent with mRNA data, protein levels of p27^{Kip1} were reduced upon MRTF depletion (Figure IV-35).

This reduction was even more pronounced after serum starvation, because unlike control cells, MRTF-depleted fibroblasts failed to accumulate the protein. p21^{Waf1} protein levels were slightly up-regulated in the cells growing in presence of 10% FBS (Figure IV-36). Under serum-starved conditions (0.2% BSA), MRTF depleted fibroblasts, unlike control cells, failed to down-regulate p21^{Waf1} protein levels. Another important regulator of G1-S transitions –

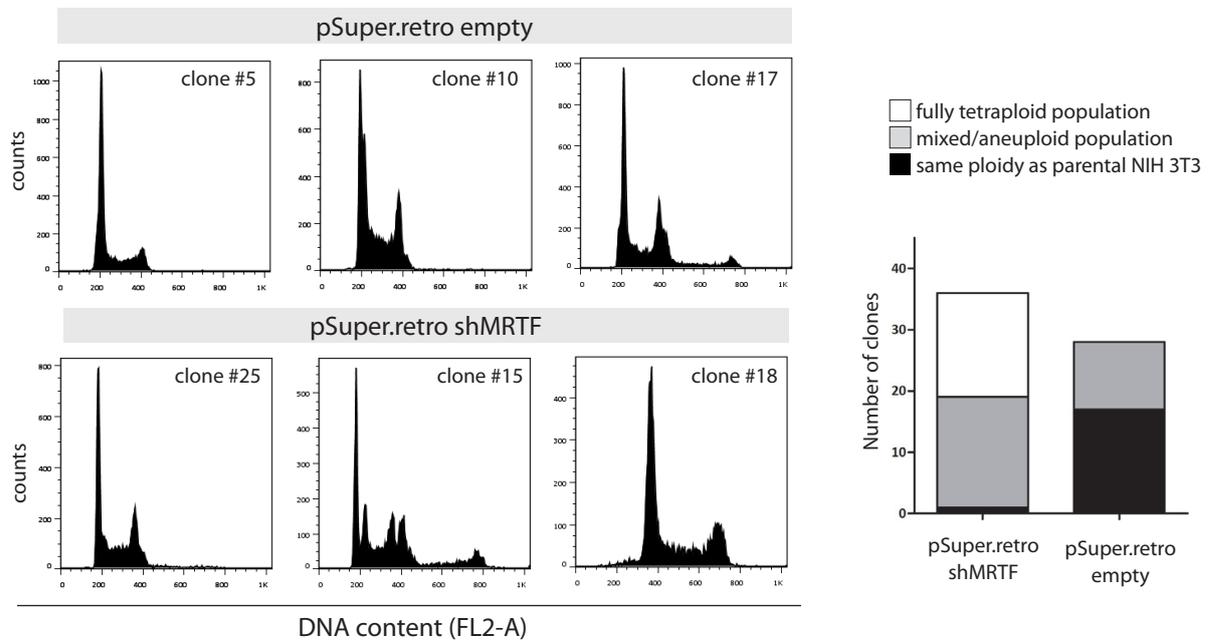

Figure IV-39: Aneuploidy in clonal lines stably expressing shRNA against MRTFs. Stable cell pools shown in Figure II-38 were sub-cloned for further 3 weeks. Monoclonal cell lines were isolated and analysed for DNA content. On the left - DNA histograms of representative clones, generated after gating out cell clumps. On the right - chart showing distribution of clones according to their DNA profile. 37 clones for shMRTF and 28 clones for pSR empty were analyzed.

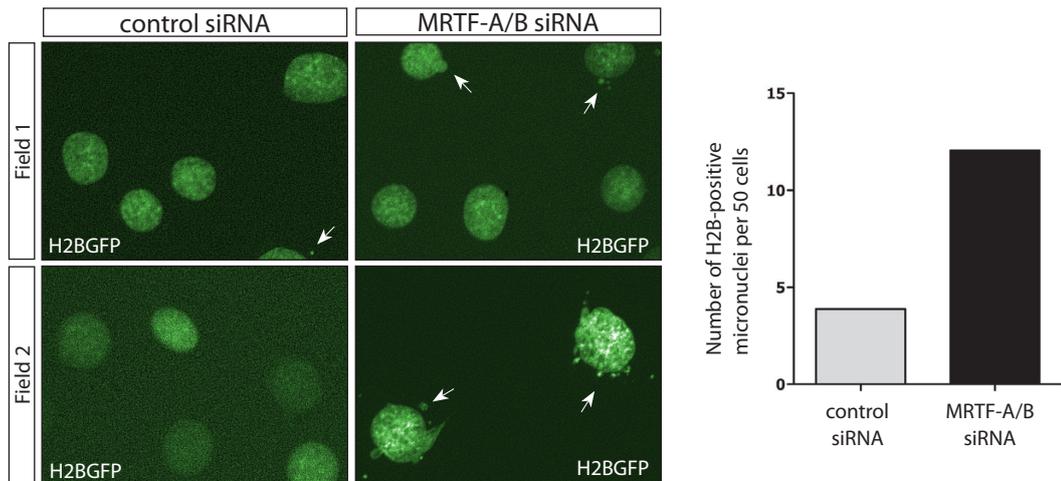

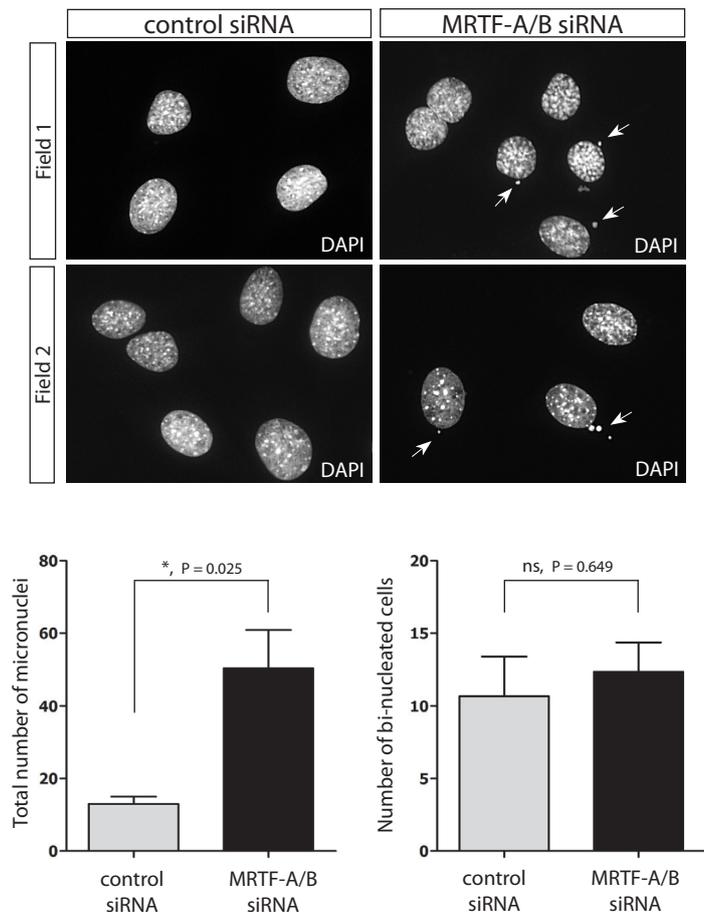

Figure IV-40: Micronuclei formation: live cell imaging of H2B-GFP. NIH 3T3 cell stably expressing H2B-GFP were transfected with the indicated siRNAs and live cell imaging was performed for 48 hours. Number of micronuclei and nuclear buds was counted at the last time point, normalised to 50 cells (graph on the right). Representative micrographs are shown on the left. Micronuclei are indicated with arrows.

Figure IV-41: Micronuclei formation: DAPI staining of fixed cells. NIH 3T3 cells were transfected either with the control siRNA or siRNA against MRTFs for 72 hours on coverslips, followed by fixation and staining with DAPI. Mironuclei/nuclear buds as well as bi-nucleated cells were counted. ≥ 200 cells analysed per sample per experiment. Results are shown in bar charts. $n=3$, bars - SEM. statistical significance is indicated on the graphs. Representative micrographs from two fields of view are shown above. Nuclear defects are indicated with arrows.

Rb protein – was not affected by the knockdown on the total protein level (Figure IV-37); however, de-activating phosphorylation on Ser⁷⁸⁰ was slightly decreased in comparison to the control at 24 hours of serum starvation, while remained comparable under full serum conditions and 48 hours of serum starvation. Levels of cyclin D1 protein changed similarly to the p21^{Waf1}, showing weak up-regulation by the knockdown in 10% FBS medium and impaired degradation in the absence of growth factors (0.2% BSA) (Figure IV-36).

In summary, observed patterns of changes in cell cycle regulatory proteins allows speculating that the shortening of G1 phase in the MRTF knockdown is potentially caused by general

down-regulation of cyclin-CDK inhibitors from CIP/KIP and INK4 families as well as slight up-regulation of cyclin D1. On the other hand, the same factors plus defective degradation of p21^{Waf1} could contribute to increase S-G2 populations in the absence of growth factors.

IV.4.5. MRTF-A/B knockdown leads to defects in chromosomal stability.

Faster progression through G1 phase, coupled with the ability to forgo G1-S arrest in serum starved conditions does not explain the anti-proliferative effect of the knockdown and the lengthening of the G2 phase. A hint for solving this phenomenon comes from analysis of the cell cycle distribution in NIH 3T3 fibroblasts stably transfected with shRNA against MRTFs. Following retroviral delivery of shRNA and selection of stable polyclonal line with puromycin for 3 weeks, the cells became aneuploid (Figure IV-38). I sub-cloned this line, together with control cells transfected with empty vector, and analyzed DNA content of individual clones. In cells, transfected with empty vector 11 out of 28 clones displayed various degrees of aneuploidisation, which points to inherent genomic instability of NIH 3T3 cell line. Interestingly,

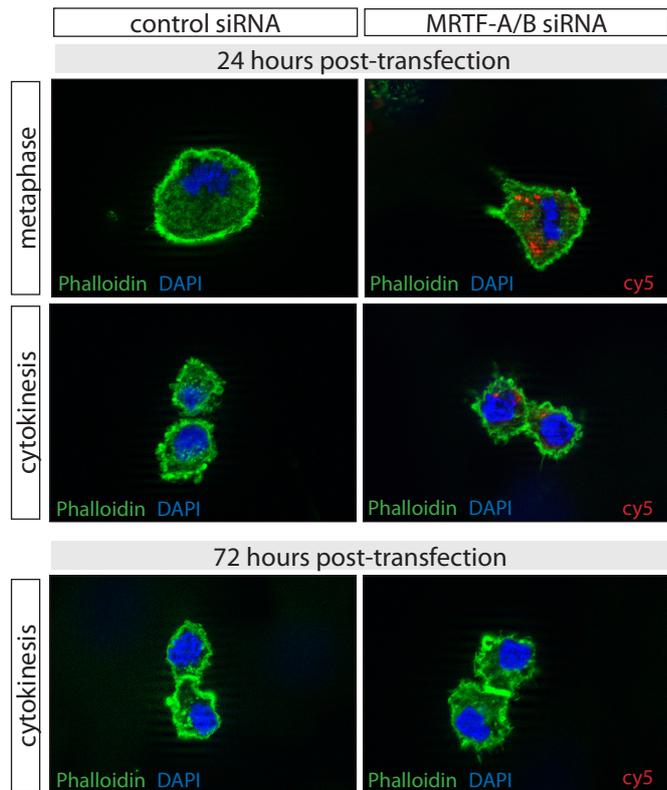

Figure IV-42: Actin cytoskeleton in dividing cells upon MRTF knockdown. NIH 3T3 cells were transfected with either control or anti-MRTF-cy5 siRNAs and incubated for 24 and 72 hours followed by staining with phalloidin and DAPI. Dividing cells were photographed at 63x magnification.

all clones expressing shRNA against MRTFs, except for one, were aneuploid with 17 out of 37 clones fully doubling their DNA content (Figure IV-39). Of note, proliferation rates of this monoclonal lines was not negatively affected by the knockdown and some of the clones apparently grew even faster than the parental NIH 3T3 cells (data not shown). Somewhat unexpectedly, I did not observe any signs of aneuploidisation in transient MRTF knockdown (data not shown), suggesting that it might be an effect requiring long-term MRTF depletion. However while performing live imaging experiments with H2B-GFP expressing cells, I noticed that MRTF-depleted cells exhibited a significant increase in mitotic defects, manifesting themselves as micronuclei and nuclear buds. This increase became apparent after more than 48 hours post-transfection; at 60 hours there was approximately 3-fold increase in cells harbouring nuclear defects (Figure IV-40). To quantify these defects, I transfected NIH 3T3 cells with either control or MRTF siRNA for 72 hours and counted cells carrying nuclear defects in fixed, DAPI-stained samples. Figure IV-41 demonstrates a significant increase in micronuclei/nuclear buds formation upon MRTF depletion, essentially confirming data from live imaging experiments. Noteworthy, at the chosen time point (72 hours), knockdown did not result in increased numbers of bi-nucleated cells. Whether these effects contribute to the impaired proliferation rate and what are the exact molecular mechanisms involved here, are still open questions. Actin cytoskeleton organization, which plays an important role in mitosis, however, did not seem to be affected during cell division of MRTF-depleted cells (Figure IV-42).

Identification of proteins competing with MRTFs for binding to G-actin.

(Performed in collaboration with dept. of Mathias Mann, MPI, Martinsried.

Collaborating partners – Marco Hein-Yannic and Christian Eberl)

Nucleocytoplasmic shuttling of MRTFs is thought to be regulated via binding of their RPEL motifs to G-actin, which is believed to mask the nuclear localization signal located between RPEL motifs (Miralles *et al.*, 2003, Posern *et al.*, 2004, Vartiainen *et al.*, 2007, Guettler *et al.*, 2008, Hirano *et al.*, 2011). Rho-mediated drop in cellular G-actin availability leads to exposure of NLS motif and subsequent nuclear accumulation of MRTFs with the help of importin α/β (Pawlowski *et al.*, 2010, Nakamura *et al.*, 2010). In addition, Crm1-dependent nuclear export of MRTF-A has been shown to be important for re-distribution of MRTF-A back to cytoplasm (Vartiainen *et al.*, 2007). However, molecular details of MRTF-G actin complex dissociation are still poorly understood. One hypothesis originating from our group suggests that G-actin is actively displaced from MRTFs by a competing G-actin-binding protein which becomes active following Rho-mediated signaling events. To identify potential candidates

that could compete with MRTFs for G-actin binding, I performed SILAC-based mass-spectrometry analysis of G-actin bound proteins before and after stimulation with serum. An indispensable tool for this experiment was the NIH 3T3 cell line which inducibly expresses FLAG-tagged G-actin upon treatment with doxycyclin (Figure IV-43). This

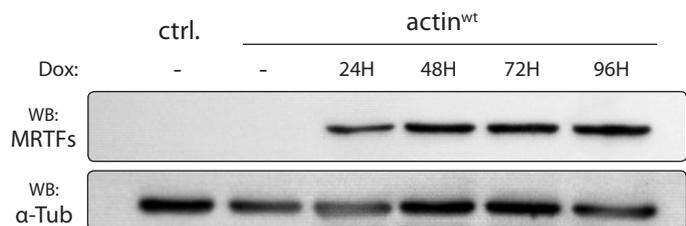

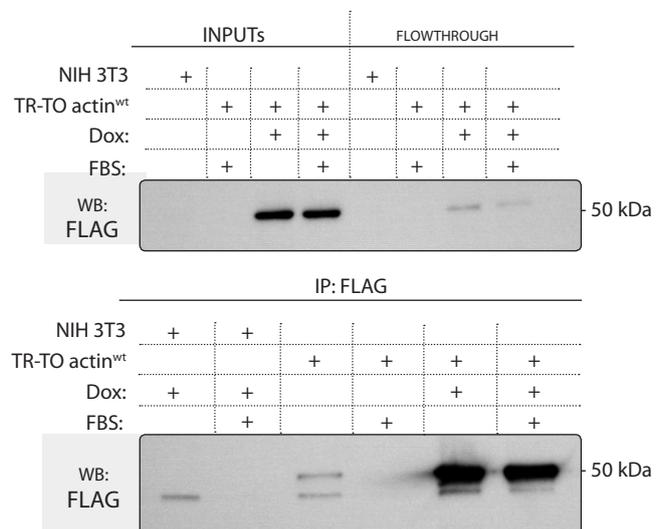

Figure IV-43: Tet-regulated expression of FLAG-tagged actin^{wt}. NIH 3T3 TR-TO empty vector (ctrl.) and NIH 3T3 TR-TO actin^{wt} cells were treated with 1 μ g/mL doxycycline for indicated periods of time. Actin was detected with anti-FLAG antibody.

Figure IV-44: co-Immunoprecipitation of FLAG-tagged actin. Either parental NIH 3T3 cells or TR-TO actin^{wt} cells were subjected to co-IP with anti-FLAG antibody as detailed in Materials and Methods section. IP efficiency is close to 90%. TR-TO actin^{wt} cell line has very little leakage in the absence of Dox (see lane 3, lower western blot). Not all samples are included in the upper picture (inputs and flowthrough).

cell line was created previously by Arnaud Descot. Experimental set-up included co-immunoprecipitation of doxycycline-induced FLAG-actin in cells either stimulated with 15% serum for 30 minutes or left untreated. Both conditions were serum-starved for 24 hours using 0.5% FBS (Figure IV-44). To identify and remove contaminating proteins, which do not come from FLAG-actin interactions, we considered using either parental NIH 3T3 cells or pcDNA4-TO empty vector monoclonal clonal cell line (both of them do not express FLAG-actin and therefore are suitable for establishing non-specific binding events). Coomassie-staining of co-IP samples (Figure IV-45) revealed little differences between the two and it was decided to use pcDNA4-TO empty vector-expressing cells as a background control. Prior to doxycycline induction and immunoprecipitation, both cell lines were labeled with either light or heavy amino acids, according to SILAC method (Ong, 2007). Light label consisted of unlabeled arginine and lysine (*R0K0*) in the growth medium, while heavy label contained $^{13}\text{C}_6$, $^{15}\text{N}_4$ -L-arginine (*R10*) and $^{13}\text{C}_6$, $^{15}\text{N}_2$ -L-lysine (*K8*). Cells were grown in the labeling medium for 6 passages which was enough to achieve more than 99% incorporation rate for heavy amino acids (Figure IV-46). Design of the experiment is shown in Figure IV-47. We used three principal conditions to compare: 1) non-stimulated empty vector and FLAG-actin expressing cells. This sample was used to define true interacting partners of actin before serum stimulation; 2) serum-stimulated empty vector and FLAG-actin expressing cells. Here we could identify true actin-interacting partners after serum stimulation; 3) non-stimulated and serum-stimulated FLAG-actin express-

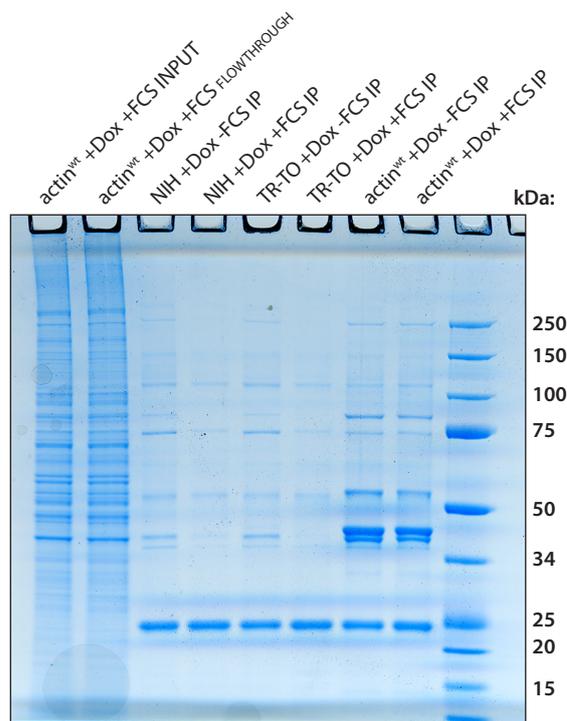

Figure IV-45: Comparison of control co-IP samples. Parental NIH 3T3, TR-TO empty vector cell line and TR-TO actin^{wt} cells were subjected to co-IP using indicated conditions and the samples were run on a gradient 4-12% polyacrylamide gel. No apparent differences between parental cells and TR-TO empty vector line are visible.

ions to compare: 1) non-stimulated empty vector and FLAG-actin expressing cells. ing cells. With this sample we were able to detect the changes in G-actin interactome after the serum stimulation. As an additional internal control, each principal sample consisted of two sub-samples mixed together – one with light label and the other one with heavy label. Immunoprecipitation samples were run on gradient polyacrylamide gels and processed for mass-spectrometry using in-gel digest protocol (Figure IV-48). Mass spectrometer handling and the analysis of the results were performed by Marco Hein-Yannic and Christian Eberl. Proteins that were identified as interactors in both empty vector and FLAG-actin expressing cells were defined as contaminants and removed from analysis. All true G-actin-interacting proteins (identified only in FLAG-actin expressing cells) were defined as 'outliers' with the calculated significance $B < 0.01$ and were taken into further analysis (Figure IV-49, marked in blue). After hierarchical clustering and sorting, proteins that were differentially bound to the FLAG-actin before and after serum stimulation were defined (Figure IV-50). In the forward ratio column green color represents proteins that display decreased binding to G-actin after serum stimulation, while red color designates increased binding to actin. Grey/black color represents no change in binding. Reverse ratio serves as internal control and should have

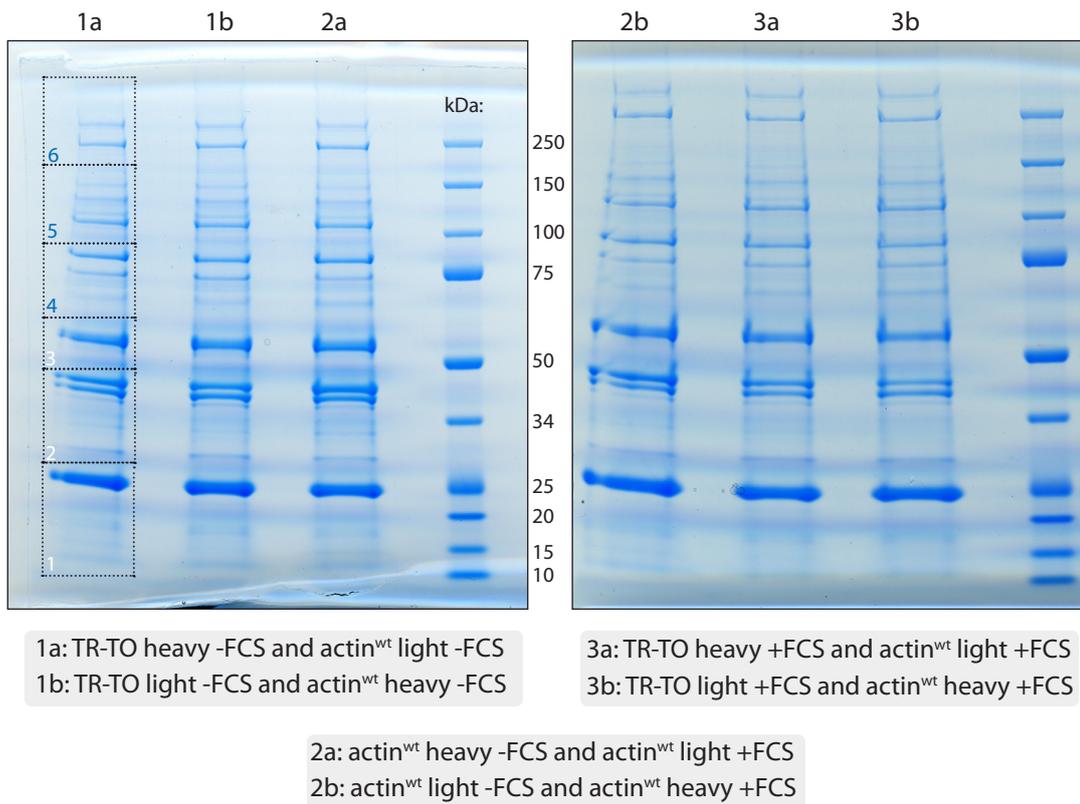

Figure IV-48: co-IP samples used in mass-spectrometry. Coomassie-stained gradient (4-12%) polyacrylamide gels with co-IP samples mixed as indicated below the pictures. First lane shows slices (numbered 1 to 6) for in-gel digestion. Actual gels used for mass-spectrometry.

the colors reversed with respect to the forward ratio. Somewhat surprisingly, only a relatively small number of proteins were found to be differentially bound to G-actin before and after the stimulation. Preliminary analysis of the data identified MRTF-A and MRTF-B as proteins

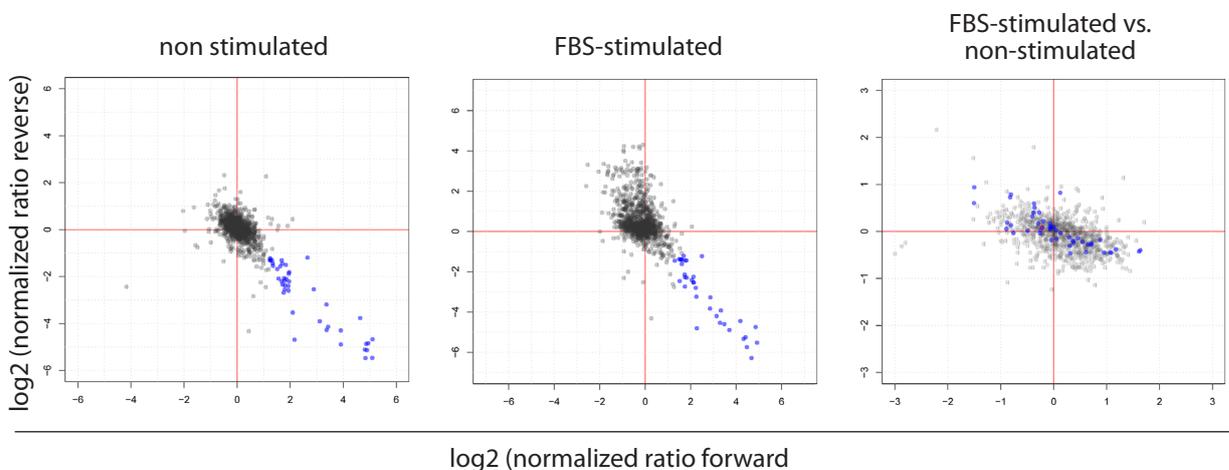

Figure IV-49: *G-actin-interacting proteins: definition.* Plot of \log_2 forward (heavy/light) ratios versus \log_2 reverse (light/heavy) ratios in non-stimulated and FBS-stimulated samples allows for identification of true *G-actin* interacting partners (they have inverted ratios). Graph on the right highlights proteins identified as true interactors; actin itself is indicated in red.

which binding to G-actin is strongly reduced upon serum stimulation - finding that gives a good indication that the results of this screen are robust. Among proteins whose binding to actin increases upon stimulation, we found all seven sub-units of the Arp 2/3 complex, which is an indispensable component of actin polymerization machinery and might be a good candidate for MRTF competitor for G-actin binding. Unexpectedly, non of the classical WH2-containing actin nucleator proteins (formins, WASP, WAVE) were identified as differentially bound to actin, possibly due to the transient nature of interaction, which could not be captured by the immunoprecipitation protocol used for this experiment. Intriguingly, one actin nucleator, Spir1, was found to be significantly less bound to G-actin after the stimulation and therefore presents an interesting observation to follow up. Several other targets in this group, for example, histones (H1a, H2b, H3), appear to be of interest not only in the context of MRTF-G-actin interaction, but also for the G-actin involvement in the regulation of transcription in general. Follow-up studies will be necessary for in-depth analysis of the results of this screen, and I provide more detailed theoretical analysis of the screen in the chapter Discussion.

Fluorescently tagged MRTF-A: characterization of the fusion proteins.

MRTF-A C-terminally fused to GFP (in pEGFP-N3 vector), as well as tetracyclin-inducible MRTF-A-GFP cell line based on NIH 3T3 have been described (Vartiainen *et al.*, 2007). In a separate project during my studies I attempted to create and characterize GFP-tagged MRTF-A isoforms in order be able to monitor anti-proliferative effects of MRTF-A in live cell imaging. This project was accomplished with a very helpful input from a practical student Lissa Princz (LMU, Munich).

First, MRTF-A protein has been found to be translated from a non-canonical codon coding for leucine, at amino acid position -92 (from ATG start codon in the reference sequence, GeneBank accession number NM_001082536.1). It has been shown that replacement of Leu -92 with methionine codon (ATG) reduces expression of MRTF-A dramatically (Miralles *et al.*, 2003). To address this, I cloned full length MRTF-A cDNA into pEGFP-N1 vector with the following modifications: a) total absence of ATG start codon in front of Leu -92; b) with ATG start codon in front of Leu-92; c) ATG codon

and Kozak sequence instead of Leu-92. Western blotting results have shown that MRTF-A-GFP fusion was expressed even without ATG codon in place, although to a much lesser extent than constructs having methionine as start codon (Figure IV-51). Moreover, addition of Kozak sequence did not influence expression levels. Next, I transiently over-expressed these fusion proteins in NIH 3T3 cells and monitored their localization. Unexpectedly, MRTF-A-GFP fusions in vast majority of the cells showed signs of severe protein aggregation, potentially localizing to Golgi apparatus in the form of dense, amorphous clusters of green fluorescence (Figure IV-52). However, cells that contained properly folded proteins, with previously described localization to cytoplasm, could also be observed. Apart from the aggregation problem, I have noticed that GFP fluorescence was significantly dimmer in MRTF-A-GFP fusions

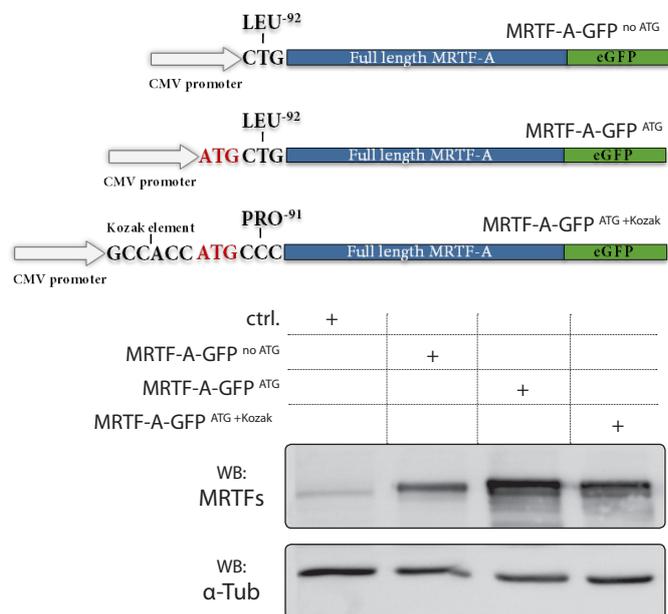

Figure IV-51: Schemes and expression test of full length MRTF-A GFP fusion proteins. Start codons and Kozak sequence are highlighted. Western blot is showing expression levels relative to the endogenous MRTFs (ctrl., empty pEGFP-N1 vector).

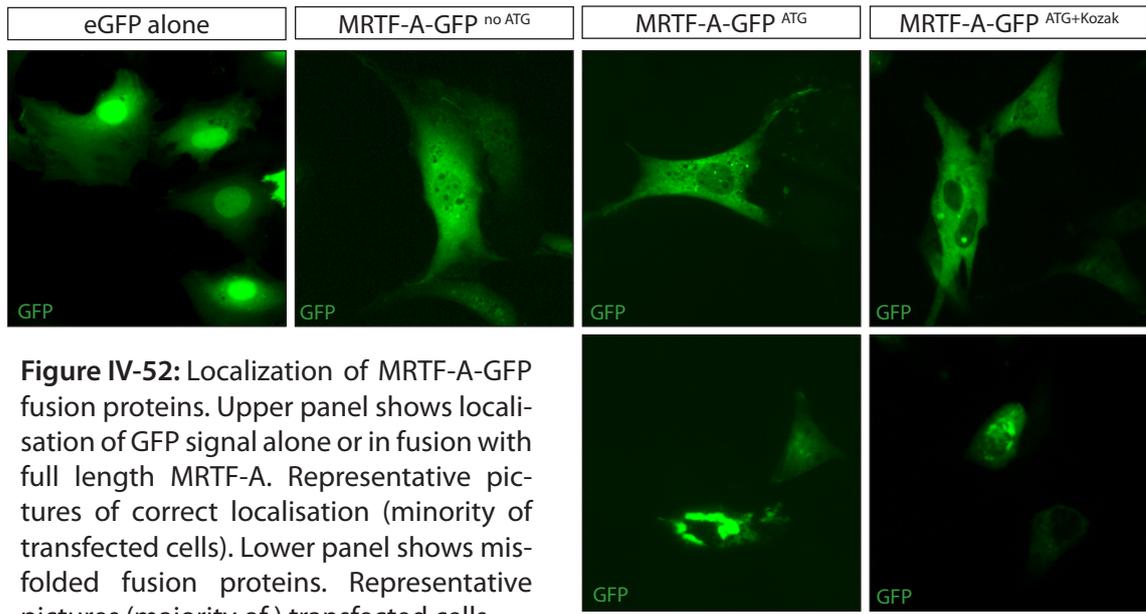

Figure IV-52: Localization of MRTF-A-GFP fusion proteins. Upper panel shows localisation of GFP signal alone or in fusion with full length MRTF-A. Representative pictures of correct localisation (minority of transfected cells). Lower panel shows misfolded fusion proteins. Representative pictures (majority of) transfected cells.

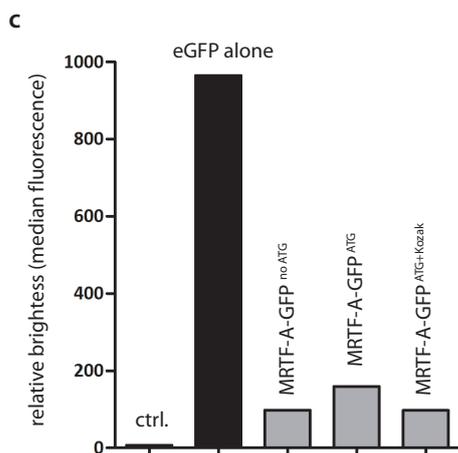

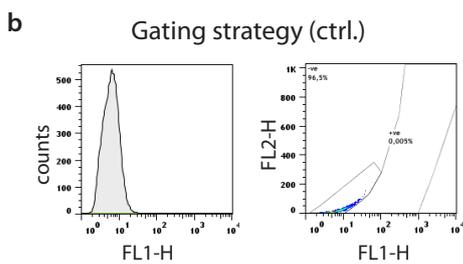

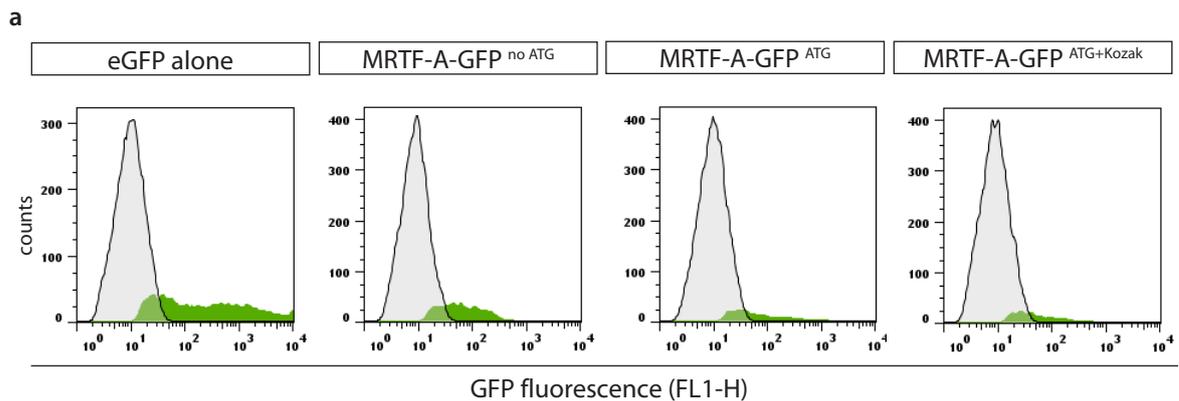

Figure IV-53: GFP brightness of full length MRTF-A-GFP fusion proteins. NIH 3T3 cells transiently transfected with the indicated fusion proteins were analysed using FACS 24 hours post-transfection. **a.** Histogram plots of GFP-positive population (in green) versus non-transfected cells (GFP-negative, in grey). **b.** Gating strategy used to create populations in **a.**, negative control (non-transfected cells) is depicted. Gates for positive and negative populations are indicated on the FL2-H vs. FL1-H scatter plot. **c.** Quantification of median fluorescence intensities of GFP channel amongst indicated samples. MRTF-A-GFP fusion proteins tend to be approximately 80% dimmer than eGFP alone.

when compared to GFP alone. To determine the extent of the fluorescence loss, I subjected transiently transfected NIH 3T3 cells to FACS analysis, which revealed that all fusion proteins were more than 80% dimmer than GFP alone (Figure IV-53). Finally, measuring SRF-MRTF transcriptional activity using luciferase assays, I have shown that all three fusion proteins caused slight basal up-regulation of SRF reporter, but failed to produce any effect upon serum stimulation (Figure IV-54). Taken together, this data suggests that, while C-terminal MRTF-A-GFP fusions could show proper localization in

some of the transfected cells, most of them turned out to be aggregated and mis-localized. Moreover, their use in functional studies does not appear to be possible, since MRTF-A transcriptional activity is severely affected by the presence of GFP next to the C-terminal transactivation domain. In addition to full length MRTF-A, I generated GFP fusions of constitutively active ΔN MAL with eGFP either on C- or N-terminus. Both of the fusions were properly expressed (Figure IV-55). Localization of C-terminal ΔN MAL –eGFP protein was similar to its full length counterpart with majority of cells displaying amorphous perinuclear staining, while some cells contained either exclusively nuclear or both nuclear and cytoplasmic protein. On the other hand, localization of N-terminally tagged eGFP – ΔN MAL in majority of cells was according

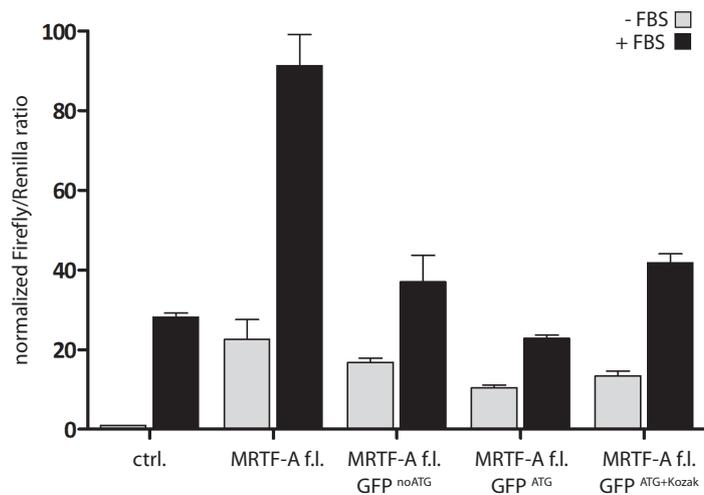

Figure IV-54: Transcriptional activity of full length MRTF-A-GFP fusion proteins. NIH 3T3 cells were co-transfected with the indicated proteins, SRF-MRTF reporter plasmid (p3D.A, expresses Firefly luciferase) and Renilla luciferase plasmid (ptkRL). Transfected cells were serum starved for 24 hours and stimulated with 15% FBS for 7 hours. Luciferase assay shows the transcriptional activity of endogenous MRTFs (ctrl, empty vector), activity of ectopic MRTF-A (MRTF-A f.l.without GFP tag) and the activities of the fusion proteins. $n=3$, bars - SEM

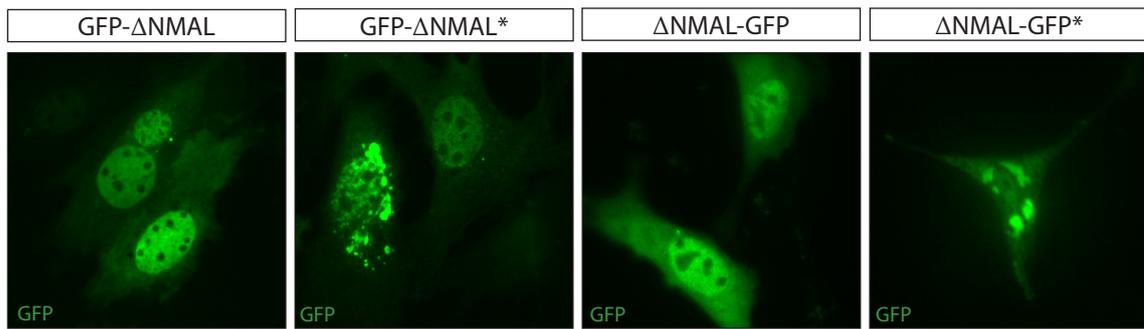

Figure IV-56: Localization of ΔN MAL-GFP fusion proteins. Representative pictures of correct localisation (minority of transfected cells) and mis-folded fusion proteins (majority of cells, indicated with asterix).

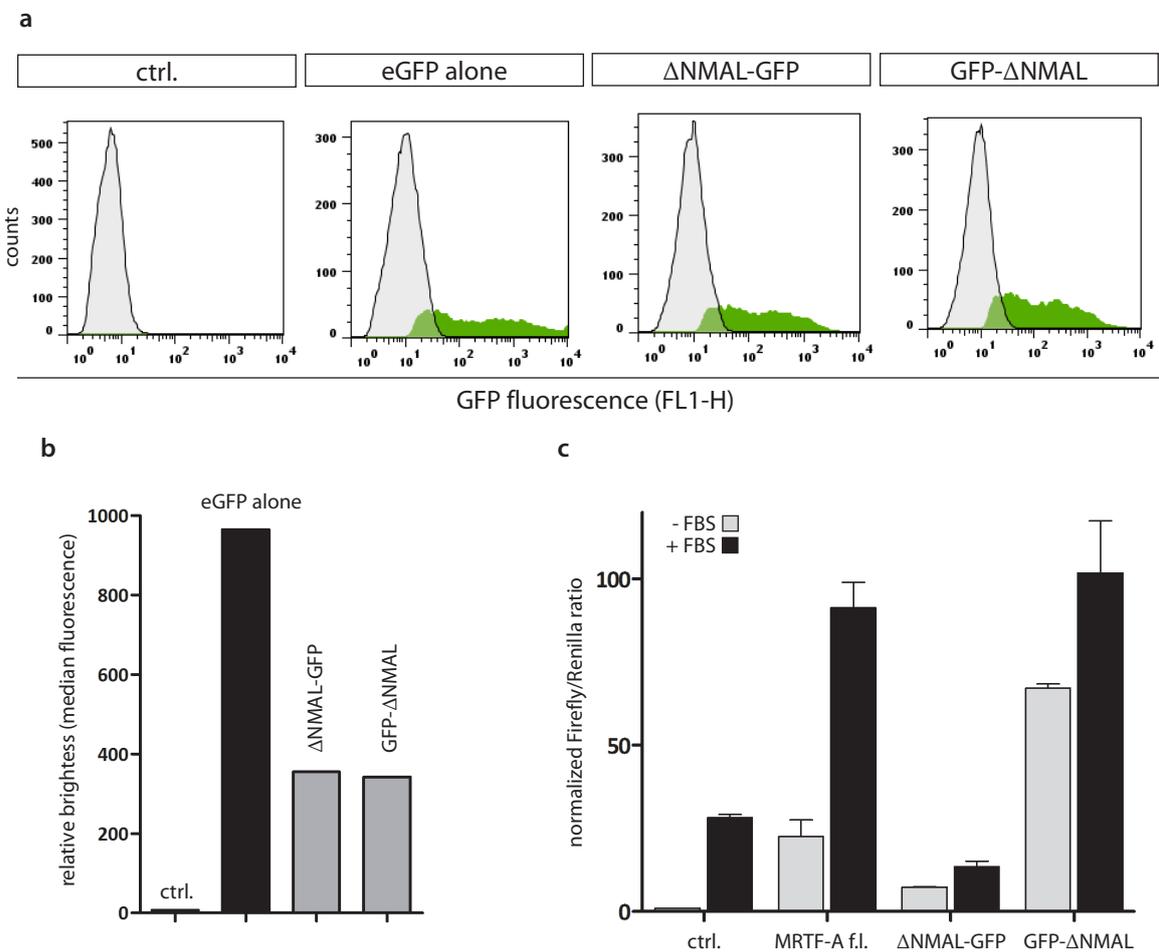

Figure IV-57: GFP brightness of ΔN MAL-GFP fusion proteins. NIH 3T3 cells transiently transfected with the indicated fusion proteins were analysed using FACS 24 hours post-transfection. **a.** Histogram plots of GFP-positive population (in green) versus non-transfected cells (GFP-negative, in grey). **b.** Quantification of median fluorescence intensities of GFP channel amongst indicated samples. ΔN MAL-GFP fusion proteins tend to be approximately 60% dimmer than eGFP alone. **c.** Transcriptional activity of ΔN MAL-GFP fusions. Samples were processed identically to Figure II-54. $n=3$, bars - SEM

to previously described – exclusively nuclear (Figure IV-56), although misfolding has also been observed. GFP brightness was also negatively affected (Figure IV-57A-B). Both N- and C-terminally tagged fusion proteins were approximately 40% as bright as eGFP alone. Transcriptional activity analysis using luciferase assays has revealed that unlike C-terminally tagged version, whose functional activity was severely impaired, N-terminally tagged eGFP- Δ N MAL displayed high transcriptional activity characteristic of constitutively active MRTF-A (Figure IV-57C). In summary, this data has indicated that eGFP orientation in MRTF-A fusions has a profound effect on transcriptional activity with N-terminally located eGFP being permissive for MRTF-A function.

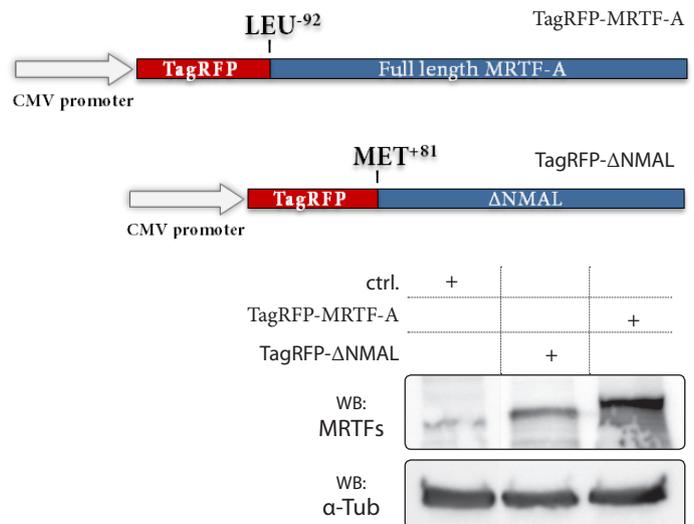

Figure IV-58: Schemes and expression test of TagRFP-MRTF fusion proteins. Western blot showing expression levels in comparison to endogenous MRTFs (ctrl.)

In an attempt to solve the problem with brightness of the fusion proteins I created N-terminal fusions of both full length MRTF-A and Δ N MAL with another fluorescent protein – TagRFP, which is the brightest monomeric red fluorescent protein (Figure IV-58). Both TagRFP-full length MRTF-A and TagRFP- Δ N MAL fusion proteins were still mislocalized and aggregated in majority of cells (Figure IV-59). Luciferase assays have shown that the activity of the full length MRTF-A was not restored by placing fluorescent protein on the N-terminus, while Δ N MAL transcriptional activity was comparable to the N-terminally tagged eGFP counterpart (data not shown).

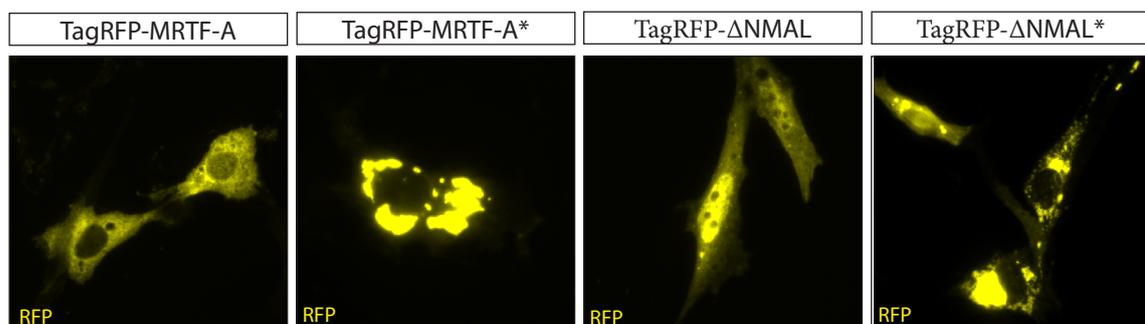

Figure IV-59: Localization of full length TagRFP-MRTF-A and TagRFP- Δ N MAL fusion proteins. Representative pictures of correct localisation (minority of transfected cells) and mis-folded fusion proteins (majority of cells, indicated with asterix).

I. DISCUSSION

Binding of SRF and MRTFs to the promoters of target genes.

Analysis of the recruitment of serum response factor and MRTFs to the promoter regions of their putative target genes have revealed several interesting observations. The majority of the consensus CArG boxes in SRF target genes have been previously identified to reside in a proximal promoter, relatively close to the transcription start site (Sun *et al.*, 2006). *In silico* analysis confirmed that the 500 base pairs upstream of TSS is indeed the area with the highest frequency of CArG boxes (Benson *et al.*, 2011). However, as a consequence of the high degree of degeneracy (1216-fold), CArG boxes can be found in other parts of the gene. In human genome, consensus CArG boxes identified within -4000 bp..+4000 bp window around transcription start site, had the following distribution: 40% in 5'-promoter region, 25% in exons, 30% in intronic regions and 6% in 5' exon UTR (Benson *et al.*, 2011). However, high occurrence of SRF-binding sites in a genome does not automatically suggest that every CArG box is a functional one. Moreover, a number of non-consensus CArG-like elements differing from the canonical sequence by 1 or more nucleotide substitutions, have been identified as true SRF-binding sites (Zhang *et al.*, 2005); some were located in the intronic regions (Chen *et al.*, 2010, Mack and Owens, 1999). In this study we have identified several patterns of SRF-MRTF binding to the target genes (Table 1). Eplin- α promoter resembles classical SRF target promoters, such as in *Cyr61*, *Vcl* and *Srf* genes with a single consensus CArG box in the immediate promoter at position -124. *Mig-6* and *Bok* genes contain a single, non-consensus CArG box in the proximal promoter (at positions -260 and -99, respectively), which is responsible for SRF-mediated transcription. *Pkp2* gene has non-canonical CArG-like element

in the immediate promoter, which does not bind SRF, however, consensus CArG box in the first intron of the gene, at position +2894, does and it is required for the SRF-mediated transcription. Genes encoding Fhl1, Pai-1 and Noxa, despite having CArG-like elements in their proximal promoters (and in the case of Noxa – consensus CArG box in the first intron), did not bind SRF or MRTFs on these elements. They were, however, regulated by the pathway similarly to the known MRTF targets (Leitner *et al.*, 2011). Probably, the most typical example of the latter phenomenon is the myocardin gene – founding member of the myocardin family. No SRF responsive element has been identified in the *myocd* gene (Sun *et al.*, 2006a), despite the presence of a single consensus CArG box at the position +6714 (Miano, 2003). Nevertheless, there is extensive evidence from SRF knockout studies pointing to the facts that myocardin is indeed a direct SRF target (Parlakian *et al.*, 2004, Miano *et al.*, 2004, Niu *et al.*, 2005).

The most challenging question arising from this data is how the position and exact sequence of SRF-binding element defines if this element will be functionally regulated by SRF. It seems there is no simple answer to this question. Nucleotide sequence surrounding CArG box is obviously important, as exemplified by the CArG-associated Ets-motif, necessary for binding of ternary complex factors (TCFs) to SRF (McMahon and Monroe, 1995). However, no such CArG-surrounding sequences have been identified for MRTF family of co-activators. One *in silico* study has proposed the existence of conserved nucleotides in the flanking regions of functional CArG boxes (at positions -15, -8, +8) that contribute to selective recognition by SRF (Wu *et al.*, 2010). Whole-genome ChIP-seq of SRF binding sites (Valouev *et al.*, 2008) has established that a large fraction of SRF peaks (29%) occurred within close proximity (100 bp) of the peaks for another transcription factor – GABP – which might indicate that on certain promoters SRF physically interacts with additional factors to form functional transcription initiation complexes. This hypothesis is further supported by the importance of TGF- β control element (TCE) in the SRF-mediated transcription of SM22 α gene (Adam *et al.*, 2000) and Sp1-binding negative element in the regulation of smooth muscle myosin heavy chain (SM-MHC) gene (Madsen *et al.*, 1997). Yet another mechanism has been described that could potentially explain SRF-MRTF dependent regulation of genes whose promoters do not contain SRF-responsive elements. Using genome-wide SRF binding profiles, Sullivan *et al.*, 2011 and He *et al.*, 2011 discovered that SRF often bind distantly located intra- or inter-genic regions; this, however, is not sufficient to activate transcription of target gene. Transcription is evidently activated by simultaneous co-occupation of the same genomic location by additional cell type-specific transcription factors. This discovery makes

SRF binding to the proximal promoters of certain genes unnecessary and therefore, impossible to detect by low throughput methods, like chromatin immunoprecipitation. In addition, higher level chromatin organization and gene modifications might have a profound effect on SRF-mediated transcription, but this area remains extremely poorly studied. We have shown that genes encoding Mig-6, Eplin- α , Pkp2 and Bok are all regulated via and physically bound by SRF and MRTFs. However, in light of the presented research, their regulation might be much more complex and cell type specific, with involvement of additional regulatory elements beside SRF-MRTFs. Genes encoding Fhl1, Pai-1 and Noxa represent good candidates for investigating regulatory mechanisms that involve binding of SRF to the distant enhancer elements.

Table I-1: Summary of serum response elements tested in this study.

Gene name	SREs tested	SRF/MRTF binding (ChiP)
Mig6	non-consensus, immediate promoter	+
Eplin- α	consensus, immediate promoter	+
Pkp2	consensus, intronic	+ (inducible SRF)
	non-consensus, immediate promoter	-
Bok	non-consensus, immediate promoter	+ (inducible SRF)
	non-consensus, immediate promoter	-
Noxa	consensus, intronic	-
	non-consensus, immediate promoter	-
Fhl1 and Pai1	non-consensus, immediate promoter	-

Additionally, I have noticed an unusual behavior of SRF on the promoters of Pkp2 and Bok. In classical cases, SRF is bound to the CArG boxes in target promoters constitutively, even in the absence of growth factors in the medium (Miralles *et al.*, 2003, Vartiainen *et al.*, 2007, Descot *et al.*, 2009). Additionally, stimulus-dependent SRF recruitment is relatively weak. However, Bok and Pkp2 promoters displayed different picture, where SRF was essentially absent from the promoter in serum-starved conditions, but became recruited to it in a stimulus-dependent manner. Evidently, this effect does not depend on the consensus/non-consensus state of the SRF-binding site, because Pkp2 contains CArG box and Bok – CArG-like element. The basis of this phenomenon is currently being investigated (<http://www.london-research-institute.org.uk/research/richard-treisman/projects>).

MRTF activity and apoptosis.

Retrovirus-mediated over-expression of active, or partially active, forms of MRTF-A confers strong cytotoxicity, accompanied by extensive cell death. It was observed on NIH 3T3 fibroblast cells and rat bladder carcinoma cell line NBT-II. Importantly, full length protein, containing all three G-actin binding RPEL domains, as well as mutants, lacking transactivation domain and RPEL domains ($\Delta N\Delta C$), or transactivation domain and SRF-binding interface ($\Delta N\Delta B$) do not affect the wellbeing of fibroblasts. These observations make obvious two facts: 1) SRF-mediated transcriptional activity is required; and 2) there is extremely tight control of MRTF-A regulation via binding to G-actin, because the degree of cytotoxicity always correlates with the number of RPEL domains present in the over-expressed protein. Literature on the effects of MRTF overexpression on cellular proliferation remains scarce. Full length MRTF-A over-expression in cardiac fibroblasts did not have any effect on their proliferation (Small *et al.*, 2010). Studies on the Drosophila homolog of MRTF-A (DMRTF) shown that the over-expression of wild-type DMRTF did not evoke any phenotype when expressed in mesoderm or tracheal system, while the effects of constitutively active DMRTF were not associated with extensive cell death, but rather with the defects in cell migration during development (Han *et al.*, 2004). Study that initially identified mouse MRTF-A (Sasazuki *et al.*, 2002) implicated its over-expression in the protection against TNF-induced apoptosis. This highly cited paper, however, contains plethora of contradictory data, which deserves mentioning here. First, all experiments were done in Traf2/Traf5 double knockout MEF cells which are extremely sensitive to TNF-induced apoptosis due to defects in NF κ B module activation (Tada *et al.*, 2001). Wild type MEFs are not susceptible for TNF-induced cell death. Since NF κ B pathway was shown to directly interact with SRF-myocardin pathway (Tang *et al.*, 2008), deleting NF κ B axis does not make interpretation of these results straightforward. Moreover, authors show that the protein they overexpress is constitutively nuclear, but translocates to cytoplasm when 500 N-terminal amino acids are deleted. This is exactly opposite from what is generally known about murine MRTF-A – it is localized to cytoplasm, but upon deletion of N-terminus, which contains RPEL motifs, re-localizes to the nucleus (e.g. Miralles *et al.*, 2003). This, together with the fact the paper could not detect interaction between SRF and the protein in question, prompts us to raise a question whether it actually was MRTF-A, that could protect the cells from TNF-induced apoptosis.

Because MRTF activity depends on the binding to SRF, it is logical to suggest that the over-expression of SRF will also lead to the same effects. However, little data on this subject does not support this hypothesis. Over-expression of constitutively active SRF was not associated with increased cells death but on the contrary, stimulated DNA synthesis and entry into cell cycle of PC12 cells (Poser *et al.*, 2000). In another study, SRF-VP16 prevented activation of caspase-3, reduced camptothecin-induced apoptosis in vitro as well as had neuroprotective effects in vivo (Stern *et al.*, 2012). In fact, the only study which has reported strong anti-proliferative effects of SRF over-expression linked this effect to non-specific consequences of high expression levels (Lin *et al.*, 2007). Phenomenon in which artificially introduced high levels of a potent transcriptional activator cause non-specific repression of transcription was termed squelching (Natesan *et al.*, 1997, Lee *et al.*, 1998). In Lin *et al.*, 2007, the authors show that SRF-mediated transcriptional squelching led to severe cytotoxicity in range of cell types, including primary MSCs (porcine bone marrow-derived mesenchymal stem cells), cardiomyocytes, Sol8 myoblasts, P19 embryonal carcinoma cells and HIIEC3 hepatoma cells. This cell death, similarly to MRTF-A induced cell death, required intact transactivation domain and was not sensitive to caspase inhibitor z-VAD-FMK. Obvious parallels between SRF-driven transcriptional squelching and constitutively active MRTF-A over-expression raise question if the latter could also be explained by the non-specific effects of high expression levels. The same paper contains evidence arguing against such a hypothesis. High levels of SRF protein in the cell repressed promoter activities not only of SRE-containing genes, but also SRE-lacking promoter targets. On the other hand, MRTF-A overexpression up-regulated transcription of target genes, pointing towards more specific mechanisms of anti-proliferative effect. Nevertheless, linking MRTF-A activity to the induction of classical apoptosis proved to be difficult. Caspase-3 was apparently activated, but to a very modest degree, which did not correlate with the extent of cell death. Moreover, pan-caspase inhibitor zVAD-FMK could not inhibit cytotoxicity. Together, the data indicates limited role of caspases in the MRTF-A mediated cell death. It is still plausible that apoptosis under these conditions takes place either without or with minimal caspase involvement at early stages – a phenomenon that have been described for staurosporine-induced cell death (Belmokhtar *et al.*, 2001). Another apoptotic marker – phosphatidylserine switch - was clearly present, although a significant portion of cells in annexin V assays also displayed damaged plasma membrane (double propidium iodide and annexin V positive cells). In apoptosis, membrane has been found to be intact throughout most part of the process and its integrity was compromised only during the final necrotic blister (Andrade *et al.*, 2010). This final stage of apoptosis has been termed

secondary necrosis (Savill *et al.*, 2002). This could serve as one explanation of the relatively big double PI-annexin V positive population of cells. Primary necrosis, on the other hand, is characterized by the compromised plasma membrane integrity at early stages. Data generated in this study does not exclude the possibility of primary necrosis occurring in parallel with true apoptosis upon active MRTF-A over-expression.

Second question that we intended to address with this study is whether MRTFs are involved in the apoptosis signaling induced by various stimuli. We show that stimulation with TNF- α , which triggers extrinsic apoptotic pathway (Budihardjo *et al.*, 1999) and a broad spectrum protein kinase inhibitor staurosporine (Chae *et al.*, 2000) increase MRTF-mediated transcriptional activity. Moreover, TNF- α does positively affect expression of MRTF-target genes in a transient manner and correlate with nuclear translocation of MRTFs. While exact consequences of staurosporine-induced MRTF activity remain obscure, TNF- α pathway has an interesting connection to SRF-mediated transcription. Upon stimulation with lipopolysaccharide (LPS), extracellular signal-regulated kinase (ERK) activates the transcription of TNF- α gene by the concerted action of several transcription factors, which include second family of SRF co-activators – Ets-1 and Elk1 (Tsai *et al.*, 2000), implicating SRF in the production of TNF- α . It is easy to suggest that secreted TNF- α acting in autocrine-paracrine manner, again induces SRF-mediated transcription, but on promoters responsive to actin-SRF-MRTF axis, instead of (or in addition to) ERK-responsive targets. Whether this activation directly relates to apoptosis induction remains to be investigated in different cell type, because neither NIH 3T3 cells nor MEFs undergo apoptosis upon TNF- α treatment due to parallel activation of pro-survival NF κ B module (Javelaud *et al.*, 2001, Tang *et al.*, 2001). Somewhat unexpectedly, another member of TNF family of ligands – TRAIL (TNF-related apoptosis-inducing ligand) – has been shown to induce caspase-dependent cleavage of SRF accompanied by loss of c-fos expression (Bertolotto *et al.*, 2000). Similar findings were reported for Burkitt's lymphoma BJAB cell line upon Fas ligation (Drewett *et al.*, 2001). This discrepancy might reflect the differences in fine-tuning of apoptotic pathways induced by similar ligands in different cellular types. Finally, it remains plausible that MRTF activity contributes to TNF- α effects other than cell death, e.g. modulation of fibroblast migration during wound healing (Schirren *et al.*, 1990).

Pro-apoptotic genes Bok and Noxa are MRTF-A targets.

In this study pro-apoptotic genes Bok and Noxa were shown to be regulated by SRF-MRTF pathway. However, physiologically relevant regulation of both genes appears to be more complex than that. Members of E2F transcription factor family have been implicated in the regulation of Bok expression upon serum-stimulated cell cycle re-entry (Rodriguez *et al.*, 2006). In comparison, our work relied on a much longer stimulation times compared to our relatively short time-scale analysis, implying different modes of Bok regulation by two serum-inducible transcription factors. In neuroblastoma cell line SH-SY5Y, but not in breast carcinoma MCF7 cells, up-regulation of Bok expression during DNA damage-induced apoptosis was found to be p53-dependent (Yakovlev *et al.*, 2004). In NIH 3T3 cells used in this study, no significant up-regulation of Bok was detected following treatment with etoposide or doxorubicin, indicating cell type and stimulus-specific regulation of Bok expression. Similarly, transcription of Noxa probably involves more than a single factor. Initially, Noxa was thought as a primary p53 target, regulated via a bona fide p53 response element in the proximal promoter, at position -195 (Oda *et al.*, 2000). However, p53-independent regulation has also been demonstrated, involving transcription factors c-myc, HIF α and members of E2F family (Elgendy *et al.*, 2011, Fei *et al.*, 2002, Lau *et al.*, 2008, Hershko and Ginsberg, 2004). Present study shows that direct activation of SRF-MRTF pathway using characterized stimuli leads to p53-independent up-regulation of Noxa gene. Moreover, depletion of p53 somewhat enhanced the regulatory pattern seen for SRF-MRTF targets and sensitized cells for latrunculin B-mediated block of induction. Consistent with this, we observed that in wild-type cells, basal levels of Noxa were slightly up-regulated by latrunculin B, which depolymerizes F-actin and this turns into slight repression in p53-depleted cells. This suggests that p53 and MRTFs could cooperate in regulating Noxa in a manner where p53 is involved in sensing F-actin status, while MRTFs respond to changes in G-actin. Unexpectedly, apoptosis-triggering etoposide and doxorubicine both induced Noxa expression, but this induction was completely abolished in p53-depleted cells. This adds a big question mark to the involvement of SRF-MRTF-mediated regulation of Noxa during DNA damage-induced apoptosis, at least in fibroblast cells. In addition, neither Bok nor Noxa could be induced by TNF- α treatment, even in the MEFs lacking NEMO protein and therefore, sensitive to TNF-induced cell death. This suggests that both genes are most likely not required for the extrinsic apoptotic signaling in the tested cells. Also, over-expression of either Bok or Noxa failed to induce cell death in NIH 3T3 fibroblasts (Shaposhnikov *et al.*, 2012 and Shibue *et al.*, 2006), pointing to the fact that both proteins do not play deciding roles in the apopto-

sis induction. The physiologically relevant link between SRF-MRTF-mediated Bok and Noxa expression and apoptosis signaling remains therefore elusive. We do not exclude the possibility that some other direct MRTF targets might play significant role in inducing cell death. For example, it has been shown that extracellular matrix protein Cyr61, which is one of the classical SRF-MRTF targets, induces apoptosis in fibroblasts (Todorovic *et al.*, 2005). It does so when used as an adhesion matrix, and does not require new transcription for apoptosis induction, implying that in our system MRTF-A-induced Cyr61 production could trigger death of the adjacent cells in a paracrine fashion.

Effects of MRTF depletion on cell cycle.

Serum response factor is without doubt a very important element in the cell cycle progression and proliferation of many cell types. It appears to be a part of the immediate early gene response (Herschman, 1991), where, upon exposure to mitogens, cells in quiescent state (G0) activate transcription factors which subsequently regulate genes necessary for G1 entry and progression through cell cycle (Almendral *et al.*, 1988, Lau and Nathans, 1985). According to this model, immediate early SRF target genes *c-fos* and *egr-1* are activated via MAP kinase pathway, involving cooperation of ternary complex factors (TCFs) and SRF (Gille *et al.*, 1992, Treisman, 1996). In addition to cell cycle entry, SRF homologue MCM1 was found to be required for G2-M transition in yeast (Althoefer *et al.*, 1995, Maher *et al.*, 1995). SRF involvement in the regulation of proliferation does not however appear to be absolutely universal: SRF-deficient mouse embryonic stem cells despite having severe defects in both immediate early gene activation and actin expression were able to proliferate normally (Schratt *et al.*, 2001). Nevertheless, presence of SRF seems to be critical for many cell types. Unlike the well-established role of ternary complex factors (Vickers *et al.*, 2004; Schratt *et al.*, 2004), the contribution of actin-regulated MRTF co-activators of SRF in this process is still not clear. During the course of this study I aimed at characterization of the effects of MRTF depletion on cell proliferation and cell cycle progression. Using siRNA, targeting both MRTF-A and MRTF-B, I essentially depleted NIH 3T3 cells from all members of MRTF family, essentially alleviating redundancy problem. Myocardin, the founding member of the family has been reported to be expressed in primary fibroblasts under certain conditions (serum starvation, contact inhibition), however, immortalized cells, like hTERT-immortalised Wi38 cell line are not able to induce its expression (Shats *et al.*, 2007; Milyavsky *et al.*, 2003). Similarly, I was not able to detect myocardin expression in cycling or serum-starved NIH 3T3 cells (unpub-

lished observations). Given the observed anti-proliferative effects of active MRTF-A over-expression together with established cytotoxic effect of myoradin expression (see above), it is logical to suggest that depletion of MRTFs will confer growth advantage to the cells. Previously, knockdown of MRTF-A and MRTF-B was shown not to affect cell cycle phase distribution when breast carcinoma MDA-MB-231 or melanoma B16F2 cells were grown in 10% FBS (Medjkane *et al.*, 2009). In the same study, knockdown also did not induce apoptosis as measured by annexin V assay. Another study has shown that MRTF-A/B-deficient neuronal precursor cells proliferate normally, but have slightly elevated levels of apoptosis (Mokalled *et al.*, 2010). In my experiments with NIH 3T3 cells, apoptosis could not be detected by Annexin V assay, while cell cycle distribution of asynchronously cycling cells remained seemingly normal. However, in growth factor-deprived conditions (0.5%) FCS, MRTF-depleted cells consistently displayed elevated S and G2 phases, which, however, did not lead to subsequent cell division and proliferation as judged by direct cell counting. Such picture can theoretically be observed under two scenarios: a) MRTF-depleted cells forgo G1-S checkpoint in the absence of mitogens present in serum; b) MRTF-depleted cells are arrested during S and G2 phases and cannot complete cell cycle upon withdrawal of growth factors. BrdU staining experiments, showing newly-synthesized DNA in serum-starved cells, fully support the first scenario. However, it is likely that there might be a second G2-M arrest, which might be a consequence of strong accumulation of p21^{Waf1} in MRTF-depleted cells, which is known to induce G2-M arrest by targeting cdc2 kinase for degradation (Dash and El-deiry, 2005). When we look at asynchronously growing cells in 10% FBS, differences in cell cycle phase distributions can only be detected by tracing single cells. And while the total time of the cell cycle progression remained unchanged, MRTF knockdown led to a significant shortening of G1 phase and slight lengthening of S-G2 phase. Exactly the same effect has been observed upon over-expression of various cyclins, for example cyclin E in primary fibroblasts (Ohtsubo and Roberts, 1993), cyclin E in HeLa cells (Wimmel *et al.*, 1994), cyclin D1 in human breast cancer T-47D cells (Musgrove *et al.*, 1994), cyclin D1 in Rat6 embryo fibroblasts (Jiang *et al.*, 1993), either cyclin E or cyclin D using tetracyclin-inducible system in Rat-1 cells (Resnitzky *et al.*, 1994). Results of this study indicate that there is only a marginal (if at all) increase in total cyclin D1 levels upon MRTF depletion, while cyclin E was not analysed. I propose, however, that identified down-regulation of the majority of cyclin-CDK inhibitor members – p18^{Ink4c}, p19^{Ink4d} and p27^{Kip1} – along with the absence of detectable p15^{Ink4b}, p16^{Ink4a} and p19ARF, increases activity of G1 cyclins, which confers effects, similar to overexpression. Concerning lengthening of S-G2 phase, potential reasons and implications have been analyzed in great

detail in Cooper, 1998 and boil down to additional effects of cyclins on S phase or unknown compensatory mechanisms. Interestingly, pharmacological inhibition of the upstream effector of MRTFs, Rho, with *C. botulinum* C3 exoenzyme, led to a very similar one hour delay in G2-M progression (Ando *et al.*, 2007), indicating that the observed effect on S-G2 phase might be MRTF-specific. Up-regulation of another member of cyclin-CDK inhibitor, p21^{Waf1} might be explained by several lines of evidence. First, p21^{Waf1} has been reported to be transcriptionally regulated by a ternary complex factor Elk1-SRF complex in a ERK-dependent manner. Given that the competition between MRTFs and TCFs exists (Wang *et al.*, 2004, Murai and Treisman, 2002), it is plausible that the absence of MRTFs could enhance the transcription of targets where such competition takes place. Alternatively, Lee *et al.*, 2007 reported that p21^{Waf1} expression is impaired in cells over-expressing SRF. They discovered that high levels of SRF led to displacement of Smad3 complex from p21^{Waf1} promoter, leading to down-regulation of protein expression. Moreover, siRNA-mediated knockdown of SRF led to increased p21^{Waf1} levels. It is not clear whether p21^{Waf1} can be expressed via MRTF activation, but its promoter does contain consensus CArG box and can be regulated via myocardin (Kimura *et al.*, 2010). Taken together, these studies allow suggesting that MRTF depletion could lead to p21^{Waf1} up-regulation via lack of repressive SRF binding to its promoter. Yet another possibility stems from the discovery that up-regulated cyclin D1 levels were found to be correlating with the increased protein stability (and consequently, accumulation) of p21^{Waf1} (Coleman *et al.*, 2003). Given that there is potential excess of free active cyclin D1 upon MRTF knockdown, as discussed earlier, it might be employed for p21^{Waf1} binding and stabilization. Finally, it has been shown that inhibition of Rho signaling lead to induction of p21^{Waf1} protein levels by Ras, while over-expression of active form of V12 H-Ras leads to p21^{Waf1} up-regulation and p27^{Kip1} repression (Olson *et al.*, 1998). These findings might serve as a potential link between upstream signaling from small GTPases and downstream SRF-MRTF axis. The effects of elevated p21^{Waf1} in MRTF-depleted cells are not clear, but apparently it does not hinder the faster progression through G1 phase.

Another prominent feature of MRTF knockdown was the accumulation of cells harbouring such nuclear defects as micronuclei and nuclear buds. Micronuclei originate from displaced chromosomes that failed to attach properly to the spindle during segregation process (reviewed in Fenech *et al.*, 2011). Interestingly, over-expression of H-Ras and subsequent activation of MAP kinase pathway also have been shown to cause increase in micronuclei count in NIH 3T3 cells (Saavedra *et al.*, 1999), along with chromosomal aberrations, such as dicentric chromosomes, acentric chromosomes, double minute chromosomes

(Denko *et al.*, 1994), improper segregation of chromosomes and exclusion of chromosomes from daughter nuclei (Hagag *et al.*, 1990). I was not able to detect increase in aneuploidy or binucleated cells on a 72 hour time scale of transient experiments, however, clonal selection of stable MRTF-depleted NIH 3T3 clones have revealed that all of them, except one, became either aneuploidy or completely doubled their DNA content. Together, these results point to the fact that MRTF depletion might severely affect a delicate balance between two signaling pathways – Ras-MAP kinase (which signal to TCFs-SRF axis) and Rho-actin pathway (which signals to MRTFs-SRF), which is necessary to maintain normal growth and proliferation of fibroblast cells.

Potential competition candidates for dissociation of G-actin-MRTF complex.

Genes whose binding to G-actin increases upon stimulation of actin-MRTF pathway are potential candidates for releasing MRTFs from inhibitory complex with G-actin. Comparing partial proteomes of NIH 3T3 cells before and after serum stimulation we were able to identify proteins that display required behaviour. For example, all seven members of actin nucleator Arp2/3 complex were detected as proteins whose binding to actin increases upon FBS stimulation. Interestingly, although it is known that Arp 2/3 complex requires nucleation promoting factors such as N-WASP or WAVE for its activity (Marchand *et al.*, 2001 Goley and Welch, 2006), none of the known NPFs were consistently found as differentially bound to actin. Counterintuitively, second type of actin nucleator, Spir1 (Quinlan *et al.*, 2005, Bosch *et al.*, 2007), was less bound to actin upon stimulation. The third known class of actin nucleators, formins (Kovar, 2006, Goode and Eck 2007), were not found as differentially bound, probably because they are mostly associated with F-actin structures and not detected in the screen. Another G-actin-sequestering protein Twinfilin-2 (but not Twinfilin-1) was found to be dissociating from G-actin following stimulation, in line with its function of limiting actin polymerization (Palmgren *et al.*, 2002). Intriguingly, increased binding of actin was detected for several histones (H2B, H4), signifying the role of nuclear actin in chromatin remodeling complexes and gene regulation (reviewed in Olave *et al.*, 2002 and Bettinger *et al.*, 2004). In conclusion, several potentially interesting G-actin-interacting proteins were found, however, more thorough experimental follow-up is required for identification of MRTF competitor for G-actin binding.

VII. ABBREVIATION LIST

- Acta2** – actin alpha 2, smooth muscle, aorta
AMKL – acute megacaryoblastic leukemia
ANF – atrial natriuretic factor
APS – ammonium persulfate
Arp2/3 complex – actin-related protein-2/3 complex
Bok – BCL2-related ovarian killer
bp – base pair
BSA – bovine serum albumin
CarG box – consensus SRF-binding site (CC(A/T)6GG)
CarG-like element – non- consensus SRF-binding site
cDNA – complementary DNA
ChIP – chromatin immunoprecipitation
CHX – cycloheximide
CMV – cytomegalovirus
Co-IP – co-immunoprecipitation
CSF-1 – colony stimulating factor 1
DIC – differential interference contrast
DMEM – Dulbecco's modified Eagle medium
DMSO – dimethylsulfoxide
DNA – deoxyribonucleic acid
E – embryonic day
EBS – Ets-binding site
eGFP – enhanced green fluorescent protein
EGFR – epidermal growth factor receptor
Egr-1 – early growth response 1 gene
Elk-1 – Ets-like transcription factor 1
ERK – extracellular signal-regulated kinase
FACS – fluorescence activated cell sorting
FBS – fetal bovine serum
FGF – fibroblast growth factor
FUCCI – fluorescent ubiquitination-based cell cycle indicator
G0, G1, S, G2, M – phases of cell cycle
GAPDH - Glyceraldehyde 3-phosphate dehydrogenase
GFP – green fluorescent protein
GPRC – G-protein coupled receptor
HeLa – cervical cancer cell line taken from Henrietta Lacks
HPRT – hypoxanthine phosphoribosyltransferase
HRP – horseradish peroxidase
IEG – immediate early gene(s)
Jasp – jasplakinolide
Kb – kilobase
kDa – kilodalton
KO – knock-out
LIMK – LIM-kinase
LPA – Lysophosphatidic acid
mAG – monomeric Azami Green protein
MAPK – mitogen-activated protein kinase
MDCK – Madin-Darby Canine Kidney cell line
mDia – murine Diaphanous
MEF – mouse embryonic fibroblast
MEF2 – myocyte enhancing factor 2
mKO2 – monomeric Kusabira Orange 2 protein
MPI – Max-Planck Institute
MRTF(s) – myocardin-related transcription factor(s)
MYOCD – myocardin
NF- κ B – nuclear factor kappa B
NLS – nuclear localization signal
P – postnatal day
PAGE – polyacrylamide gel electrophoresis
Pai-1 – plasminogen activator inhibitor 1
PBS – phosphate buffered saline
PCR – polymerase chain reaction
PDGF – platelet-derived growth factor
PVDF – polyvinylidene fluoride
Rb – retinoblastoma protein
RFP – red fluorescent protein
RFP – red fluorescent protein
RIPA – radioimmunoprecipitation assay buffer
RNA – ribonucleic acid
ROCK – Rho-associated protein kinase
RPEL – actin-binding protein domain with consensus sequence RPxxxEL
SAP – SAF-A/B Acinus PIAS DNA-binding domain
SCAI – suppressor of cancer cell invasion
SDS – sodium dodecyl sulfate
SEM – standard error of the mean
shRNA – small hairpin RNA
SILAC – stable isotope labeling by amino acids in cell culture
siRNA – small interfering RNA
SM – smooth muscle
SM-MHC – smooth muscle myosin heavy chain
SRE – serum response element
SRF – serum response factor
SUMO – small ubiquitin-related modifier
TCF(s) – ternary complex factor(s)
TGF- β – tumor growth factor β
TNF- α – Tumour necrosis factor α
TPA – phorbol ester 12-O-tetradecanoyl-13-acetate
Traf – TNF-receptor-associated factor
UTR – untranslated region
WB – western blot
wt – wild type

VIII. LIST OF PUBLICATIONS

Parts of this dissertation were published in the following peer-reviewed works:

Descot A, Hoffmann R, Shaposhnikov D, Reschke M, Ullrich A, Posern G. 2009. Negative regulation of the EGFR-MAPK cascade by actin-MAL-mediated Mig6/Errfi-1 induction. *Molecular cell* **35**:291–304.

Leitner L, Shaposhnikov D, Descot A, Hoffmann R, Posern G. 2010. Epithelial Protein Lost in Neoplasm alpha (Eplin-alpha) is transcriptionally regulated by G-actin and MAL/MRTF coactivators. *Molecular cancer* **9**:60.

Leitner L, Shaposhnikov D, Mengel A, Descot A, Julien S, Hoffmann R, Posern G. 2011. MAL/MRTF-A controls migration of non-invasive cells by upregulation of cytoskeleton-associated proteins. *Journal of cell science* **124**: 4318-31.

Shaposhnikov D, Descot A, Schilling J, Posern G. 2012. Myocardin-related transcription factor A regulates expression of Bok and Noxa and is involved in apoptotic signaling. *Cell Cycle* **11**:141–150.

Shaposhnikov D, Kuffer C, Storchova Z, Posern G. 2013. Myocardin-related transcription factors are required for the coordinated cell cycle progression (submitted to *Cell Cycle*).

IX. ACKNOWLEDGEMENTS

First, I would like to thank Prof. Dr. Guido Posern for giving me the opportunity to work on this interesting project, for his scientific input, helpful discussions, support and general mentoring throughout my time in his laboratory.

I thank Prof. Dr. Elmar Wahle from the University of Halle who very kindly accepted to be my official supervisor at the University.

The former members of the Posern lab Arnaud Descot, Laura Leitner and Stephan Busche I would like to thank for all the collaborations we undertook and for making the atmosphere in the lab relaxed, but at the same time productive.

I would like to express my gratitude to the members of my advisory committee, Prof. Dr. Peter Becker, Dr. Marc Schmidt-Supprian, Prof. Dr. Gunter Meister and Dr. Zuzana Storchova for their advice and support during my studies.

I thank the members of the M.Mann department of MPI of Biochemistry – Marco Hein-Yannic and Christian Eberl – for the excellent collaboration project and their professional attitude.

Members of Z. Storchova lab, Christian Kuffer and Anastasia Kuznetsova, I would like to thank for helpful discussions and for sharing with me their expertise in live cell imaging.

I would like to thank my practical students Lissa Pincz and Peter Sinner. It was a real pleasure to work with you. Alexander Mengel I would like to thank not only for being an integral part of our lab during his master thesis, but also for excellent badminton matches after work!

Current members of the Posern lab Patricia Eisenach, Julia Weissbach, Franziska Schikora, Falk Pohl, Ulrich Blache, Astrid Vess, Anja Weber, Victoria Schröder I thank for being awesome labmates! Robert Torka and Simone Gusenbauer I thank for making our office at MPI probably the coolest one in the whole institute!

For facilitating my scientific and non-scientific experiences in Munich and Halle, I would like to thank all members, past and present of the Ullrich department of MPI, Daniel Wilson lab and their friends from Gene Center of LMU, and the members of Institut für Physiologische Chemie in Halle.

Last, but not least, I am grateful to my family and Maria Wagner for their continuous support, encouragement and being there for me at all times.

This work was financially supported by the Deutsche Forschungsgemeinschaft (DFG).

Eidesstattliche Erklärung

Hiermit erkläre ich an Eides statt, dass die vorliegende Arbeit selbstständig und nur unter Benutzung der angegebenen Quellen und Hilfsmittel erstellt wurde. Die Stellen, die anderen Werken wörtlich oder sinngemäß entnommen sind, sind als solche kenntlich gemacht. Ich versichere weiterhin, dass die Arbeit in gleicher oder ähnlicher Form noch keiner anderen Prüfungsbehörde vorgelegen wurde.

Halle (Saale), den 21.04.2013

Dmitry Shaposhnikov

Lebenslauf

Name/Vorname:	Shaposhnikov Dmitry
Adresse:	Carl-von-Ossietzky-Straße 16, 06114 Halle (Saale)
Geburtsdatum/Ort:	03 März 1984 in Kaliningrad, UdSSR
Staatsangehörigkeit:	Russische Föderation
Familienstand:	ledig
Email:	dmitry.shaposhnikov@medizin.uni-halle.de

Akademische Ausbildung. Forschungstätigkeit

10.2008 - heute

Doktorand am Max-Planck Institut für Biochemie (Martinsried). Seit 05.2012 - an der Martin-Luther-Universität Halle-Wittenberg, Institut für Physiologische Chemie. **Thema:** The role of myocardin-related transcription factors in proliferation and cell cycle regulation of fibroblast cells".

01.2007 - 05.2008

Gaststudent/Gastwissenschaftler (Aufbaustudium) am Imperial College London, Ovarian Cancer Forschungszentrum. **Thema:** "Molecular mechanisms of action behind a new tumour suppressor gene OPCML"

10.2005 - 01.2007

Doktorand am Forschungsinstitut für Mikrobiologie und Epidemiologie, Minsk, Weißrussland. **Thema:** "Construction and immunological analysis of bacterial ghosts carrying exposed hantaviral nucleocapsid proteins".

05.2005 - 10.2005

Wissenschaftlicher Mitarbeiter am Forschungsinstitut für Mikrobiologie und Epidemiologie, Minsk, Weißrussland.

24.06.2005

Abschluss Diplom in Biologie und Biotechnologie an der Weißrussische Staatlichen Universität, Minsk, Weißrussland (Note: 1.0). Titel der Diplomarbeit: "Immunological analysis of a recombinant peptide composed of repetitive sequences of antigenic determinants of Puumala virus".

09.2000 - 06.2005

Studium an der Weißrussische Staatlichen Universität, Minsk, Weißrussland. Fächer: Biologie, Biotechnologie, Biochemie.

Ausbildung

09.1998 - 06.2000

Abitur am Lyzeum der Weißrussische Staatliche Universität. Leistungskurse: Biologie, Chemie
