1. Introduction

The human FK506-binding protein 38 (FKBP38) is a constitutively inactive peptidyl prolyl *cis/trans* isomerase (PPIase) that is activated by calmodulin (CaM) and calcium (Ca²⁺). Furthermore, this protein plays a key role in Bcl-2 related apoptotic pathways (Edlich et al., 2005; Edlich et al., 2006). Because of all these singular properties, the molecular structure of FKBP38 and the characterization of its interaction with CaM are of major interest.

1.1. PPIases

Proteins play a fundamental role in virtually every biological process, displaying a multitude of functions such as the catalysis of biochemical reactions, the transmission of biological messages in signal transduction pathways, and the trafficking of a wide variety of chemical substances across cell membranes. All proteins are synthesized in the ribosome as linear polypeptide chains. In order to become biologically active, the polypeptide chain has to fold into a unique native three-dimensional structure. Moreover, the failure of proteins to fold correctly and efficiently is associated with the malfunction of biological systems. A variety of diseases such as cystic fibrosis and Alzheimer's disease are the result of protein misfolding (Chaudhuri and Paul, 2006; Cohen and Kelly, 2003).

Although the information for correct folding is encoded by the amino acid sequence for most proteins (Anfinsen, 1973), living organisms are additionally equipped with an efficient folding machinery, consisting of chaperones (Bukau et al., 2006; Hartl, 1996), protein disulfide isomerases (Ellgaard and Ruddock, 2005) and peptide bond isomerases (Fischer, 1994; Fischer and Aumüller, 2003).

Peptide bond isomerases assist the *cis/trans* interconversion of peptide bonds, which possess partial double bond character due to the delocalization of the lone electron pair of the nitrogen atom across the entire amide group. Peptide bonds therefore can only adopt two planar conformations (*cis* or *trans*), which interconvert slowly in comparison with the other torsion angles that define the protein conformation. There are two classes of peptide bond isomerases: (i) the secondary amide peptide bond isomerases (APIases) (Schiene-Fischer et al., 2002) and (ii) the major class of the peptidyl prolyl *cis/trans* isomerases (PPIases, Enzyme class 5.2.1.8.) (Fischer et al., 1989) which assists the interconversion of peptide bonds where proline is in the C-terminal position.

PPIases are ubiquitous in life. The subfamilies of this enzyme class (i) are unrelated to each other in their amino acid sequences, (ii) have distinct substrate specificities, and (iii) prove to be sensitive to different inhibitors. A classification of these enzymes according to their ligand-specificity and sequence similarities allows the identification of three PPIases families: the FK506-binding proteins (FKBPs), the cyclophilins (CyPs) and the parvulins. The members of the first two families are characterized by their ability to bind the low-molecular-weight compounds FK506 (also known as tacrolimus) and cyclosporin A (CsA), producing highly immunosuppressive complexes that lead to the inhibition of T-cell proliferation. Therefore PPIases of these two families are also referred to as immunophilins.

Although no sequence homologies exist between the three PPIase families, the structure of the active site is very similar in all of these enzymes, suggesting that the catalytic pathway utilized by FKBPs, cyclophilins and parvulins is closely related. Albeit several fundamental parameters describing the enzymatic catalysis mediated by PPIases are different, a common pattern of structural motifs has been found in the three-dimensional structures of FKBP and parvulin domains, leading to the definition of an FKBP-like superfold (Sekerina et al., 2000). Hence, the question of how catalysis is carried out by these enzymes still remains open (Fanghänel and Fischer, 2004).

PPIases can consist of one or more PPIase domains, complemented by additional functional segments, such as protein-interaction domains/sites and membrane anchors. These additional segments have been found both N-terminal and C-terminal to the catalytic domain (Galat, 2004a,b) and may account for the regulation and specific localization of the enzymes.

Besides the catalysis of peptidyl prolyl *cis/trans* isomerization, which can play a role in *de novo* protein folding (Brandts et al., 1975; Wedemeyer et al., 2002), native state isomerization (Andreotti, 2003) and signal transduction (Wulf et al., 2005; Lin and Lechleiter, 2002), additional molecular mechanisms have been reported for the physiological function of PPIases. They can act, for example, as presenter proteins in immunosuppression when they bind low-molecular-weight immunosuppressants such as CsA and FK506. The PPIase-inactive Cyp18/CsA and FKBP12/FK506 complexes are able to bind and subsequently inhibit the role of the protein phosphatase calcineurin (protein phosphatase 2B, CaN) in signal transduction events that lead to T-cell proliferation (Vogel et al., 2001; Liu et al., 1991; McCaffrey et al., 1993; Shibasaki et al., 1996). Remarkably, only the immunosuppressant/PPIase complexes and not the individual PPIases or immunosuppressants are able to display this affinity to CaN in what is called a “gain of function” mechanism. A proline-directed binding function and a holding

function for unfolded polypeptide chains are other reported mechanisms of action of PPIases (Fischer and Aumüller, 2003).

1.1.1. Human FKBP

A total of 16 different FK506-binding proteins have been reported in human cells (Figure 1). Members of this enzyme family can be found in all human tissues. The majority of them are multidomain proteins, consisting of one or more FKBP domains as well as different signal sequences and protein-interaction domains, such as tetratricopeptide repeat (TPR) domains and calmodulin binding sites (Galat, 2004b). In some FKBP with multiple FKBP domains, PPIase activity has been found only in the first N-terminal FKBP domain when using the standard PPIase assay (Barent et al., 1998). Common characteristics of all constitutive active human FKBP are (i) the PPIase activity, (ii) the binding of the macrolide FK506, and (iii) the inhibition of CaN by the formation of the FKBP/FK506/CaN complex (Weiwad et al., 2006).

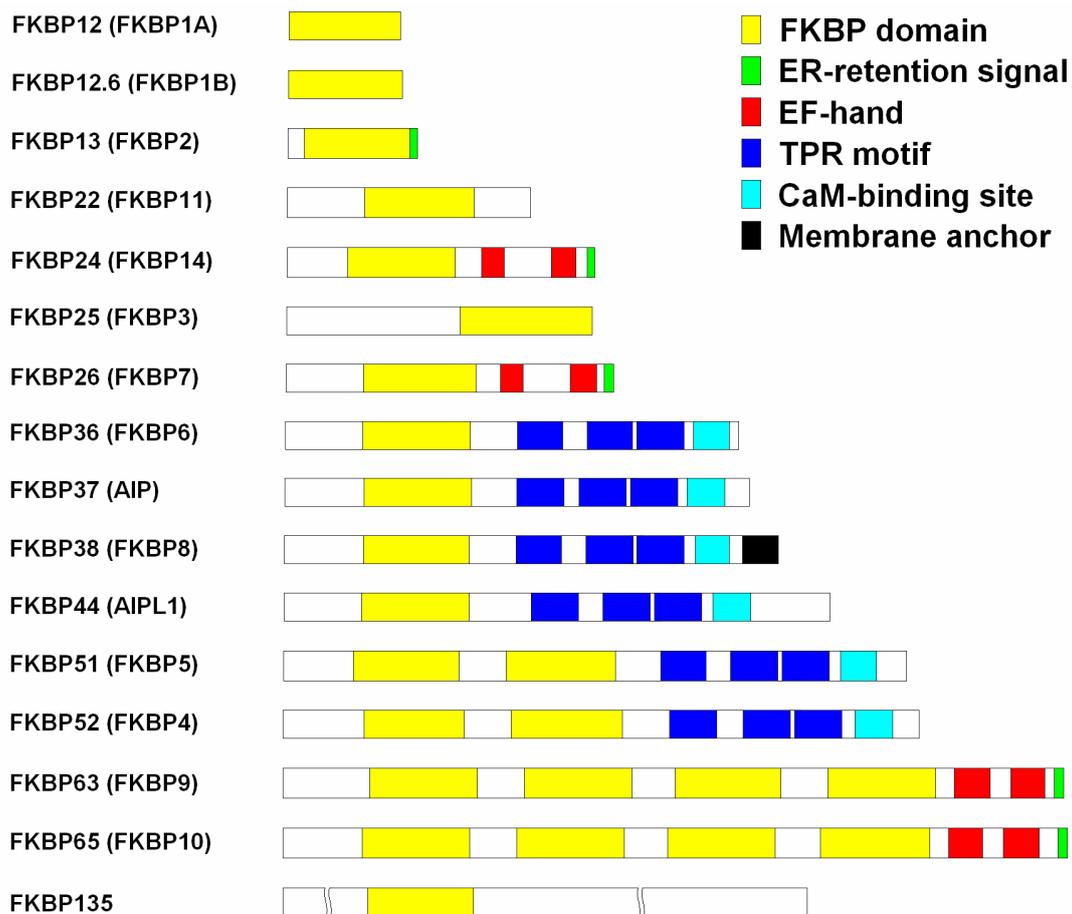

Figure 1. Schematic representation of the human FKBP and their domain structures. The gene names are shown in the brackets. Kindly provided by Dr. Frank Edlich.

A variety of physiological functions have been assigned to FKBP. They are involved in

spermatogenesis (Crackower et al., 2003), Ca^{2+} homeostasis (Wehrens et al., 2004) as well as Bcl-2-dependent apoptotic pathways (Edlich et al., 2005) and cytoplasmic receptors (Pratt et al., 1999). Mutations in FKBP genes are related to the occurrence of congenital diseases such as the Williams Beuren syndrome (WBS, OMIM 194050) and the Leber congenital amaurosis (LCA, OMIM 204000) (Meng et al., 1998; Sohocki et al., 2000; Ramamurthy et al., 2003).

Another relevant biological feature of the PPIases concerns the effects of their complexes with the low molecular compounds FK506 and rapamycin (a secondary metabolite from *Streptomyces higroscopicus*) on the signal pathways of cell proliferation. In a fashion similar to the previously described role of the FKBP12/FK506 complex in the inhibition of T-cell proliferation, the complex of FKBP12 and rapamycin inhibits the protein kinase mTOR (mammalian target of rapamycin) (Sabers et al., 1995). This inhibition of mTOR in turn interferes with the activation of the phosphatidylinositol 3-kinase/protein kinase B (PI3K/Akt) signal pathway (Fingar and Blenis, 2004), thus also inhibiting T-cell proliferation.

1.1.2. The human FKBP38

The human FKBP38 (gene name FKBP8) was first characterized as a result of a very pronounced expression of its corresponding mRNA in neuronal cells (Lam et al., 1995). The protein consists of 355 amino acids, which are organized in an N-terminal FKBP domain, a TPR domain consisting of three TPR motifs and an associated putative calmodulin-binding site, and a C-terminal membrane anchor that is unique among human FKBP and leads to the localization of FKBP38 in the membranes of the endoplasmic reticulum and the mitochondria (Edlich et al., 2005; Wang et al., 2006). A similar domain organization has also been found in FKBP42 from plants (Kamphausen et al., 2002). The first 34 residues in the FKBP38 sequence, located N-terminal to the FKBP domain, are supposedly non-structured based on secondary structure predictions. A report, however, indicates that FKBP38 derives from a truncated ORF (open reading frame), and that the extended form of this protein would present an extra N-terminal segment of 57 residues, thus comprising 412 amino acids and reaching a molecular weight of 45 kDa (Nielsen et al., 2004).

FKBP38 was originally reported as an inherent calcineurin inhibitor, suggesting that it is the only immunophilin able to inhibit the phosphatase activity of CaN and thus to interfere with the CaN/NFAT pathway in the absence of FK506 (Shirane and Nakayama, 2003). Later reports, however, clearly demonstrated that in the absence of bound FK506 FKBP38 does not inhibit CaN, ruling out a possible role as endogenous CaN inhibitor (Kang et al., 2005; Weiwad et al.,

2005). Only the CaM/Ca²⁺/FKBP38/FK506 complex can inhibit CaN, but to a much lower extent than FKBP12, FKBP12.6 or FKBP51 (Weiwad et al., 2006). An indirect effect of FKBP38 on the subcellular localization of CaN, which is mediated by typical CaN ligands such as B cell lymphoma protein 2 (Bcl-2), was also reported (Weiwad et al., 2005).

A remarkable property of FKBP38 is the lack of constitutive FKBP activity of its FKBP domain. Thus, this protein cannot bind FK506 or catalyze the peptidyl prolyl *cis/trans* isomerization by itself (Edlich et al., 2005; Kang et al., 2005). Moreover, the enzymatic activity of this protein is regulated by CaM/Ca²⁺, which is a unique property among human FKBP. Only the CaM/Ca²⁺/FKBP38 complex exhibits PPIase activity and is able to bind FK506 (Edlich et al., 2005).

The active form of FKBP38 interacts with Bcl-2, which is known to be a key player in the control of apoptosis. The formation of the Bcl-2/FKBP38/CaM/Ca²⁺ complex interferes with the binding of Bcl-2 to its cellular targets, such as CaN or Bad. Thus, the active form of FKBP38 participates in apoptosis control by inhibition of the anti-apoptotic Bcl-2 function (Figure 2) (Edlich et al., 2005). The formation of the Bcl-2/FKBP38/CaM/Ca²⁺ complex can be prevented by application of low-molecular-weight FKBP38 inhibitors. In fact, the inhibition of FKBP38 by active site-directed ligands or the reduction of cellular FKBP38 levels by FKBP38 RNAi in neuroblastoma cells resulted in a prevention of apoptosis that is induced by etoposide, daunorubicin, camptothecin or ionomycin (Edlich et al., 2005). This result strongly suggests a role of FKBP38 in the regulation of apoptosis in neuronal systems. Moreover, the specific FKBP38 inhibitor N-(N',N'-dimethylcarboxamidomethyl)cycloheximide (DM-CHX) has demonstrated neuroregenerative and neuroprotective properties in a rat model of transient focal cerebral ischemia (Edlich et al., 2006). The fact that FKBP38 also influences the cell size regulation by the human tumor suppressor proteins (TSC) (Rosner et al., 2003) is another indication of the key role of FKBP38 in the regulation of apoptosis in neuronal cells.

A number of results have been published suggesting an anti-apoptotic function of FKBP38 in HeLa cells. Thereby, FKBP38 was suggested to target Bcl-2 to the mitochondria (Shirane and Nakayama, 2003), and to play a role in the folding and stabilization of Bcl-2 (Kang et al., 2005). The interaction of presenilins with FKBP38 was claimed to promote apoptosis by reducing the levels of mitochondrial Bcl-2 (Wang et al., 2005). Furthermore, the down regulation of FKBP38 with siRNA was associated with the activation of caspase-3 dependent apoptosis (Kang et al., 2005). The controversial duality of this protein as both pro-apoptotic and anti-apoptotic regulator has been attributed to the different cell lines used in the different studies (Kang et al., 2005).

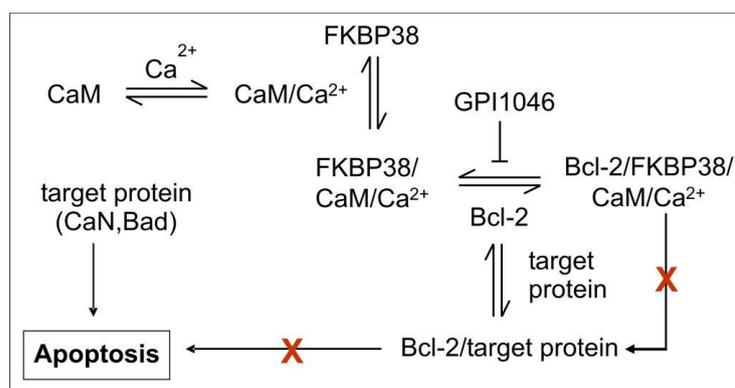

Figure 2. Model of the regulation of apoptosis by FKBP38 in neuroblastoma cells. First, the increase of the cytoplasmatic Ca^{2+} -concentration produces an activation of CaM in form of $\text{CaM}/\text{Ca}^{2+}$. Then, the $\text{FKBP38}/\text{CaM}/\text{Ca}^{2+}$ complex is formed, which subsequently inhibits Bcl-2 by the formation of the $\text{Bcl-2}/\text{FKBP38}/\text{CaM}/\text{Ca}^{2+}$ complex. In case of apoptosis induction, the inhibited Bcl-2 cannot bind its pro-apoptotic targets, and their activity can therefore lead to apoptosis. The inhibition of Bcl-2 by the $\text{FKBP38}/\text{CaM}/\text{Ca}^{2+}$ complex can be prevented by application of specific FKBP38 inhibitors, such as GPI1046. Kindly provided by Dr. Frank Edlich.

The active form of FKBP38 (i.e. the $\text{FKBP38}/\text{CaM}/\text{Ca}^{2+}$ complex) has furthermore been found to interact with Hsp90 in a similar manner as other FKBP38s with TPR domains such as for example FKBP51 (Okamoto et al., 2006; Edlich et al., 2007). This interaction is mediated by the TPR domain of FKBP38 and the C90 domain of Hsp90 (Edlich et al., 2007). However, it leads to the inhibition of the FKBP activity of FKBP38, probably as a consequence of steric hindrance between Hsp90 and the ligands of the FKBP domain.

Finally, an interaction of the hepatitis C non-structural protein NS5A with FKBP38, which leads to the prevention of apoptosis, was recently reported (Wang et al., 2006). A Bcl-2 homology (BH) domain present in NS5A was identified as the one responsible for the interaction with FKBP38.

1.1.3. Three-dimensional structures of FKBP38s

1.1.3.1. The prototypic FKBP12

Human FKBP12 (FKBP12; gene name FKBP1A) is the best characterized member of the FKBP enzyme family. This protein represents the minimal amino acid sequence displaying PPIase activity and FK506 binding, and is therefore considered as the prototypic FKBP domain. It folds to a “half β -barrel” that consists of a five-stranded antiparallel β -sheet (with a +3, +1, -3, +1 topology) which wraps around a central α -helix and encloses the active site (Figure 3A). Several three-dimensional structures of this protein and its complexes with FK506, rapamycin and other low-molecular-weight ligands have been solved by means of NMR and X-ray crystallography

(Michnick et al., 1991; Van Duyne et al., 1991a,b; Van Duyne et al., 1993; Wilson et al., 1995; Sich et al., 2000). On the other hand, no structure of an FKBP12 complex with a peptide substrate has been solved up to date.

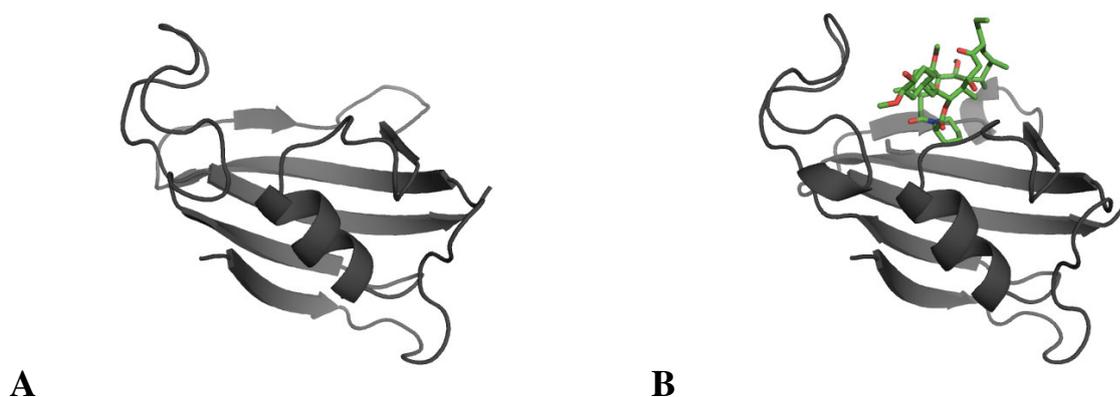

Figure 3. Comparison of the three-dimensional structures of (A) FKBP12 and (B) the FKBP12/FK506 complex. The FK506 molecule is represented as stick model and colored according to atom type.

No major structural changes arise in FKBP12 upon FK506 binding. In the FKBP12/FK506 complex (Figure 3B), the FK506 molecule binds in a hydrophobic cavity located between the interior side of the β -sheet and the α -helix, flanked by the loops β 2- β 3 and β 5- α 1 as well as the bulge disrupting β 5. A total of fourteen residues (Tyr26, Phe36, Asp37, Arg42, Phe46, Glu54, Val55, Ile56, Trp59, Ala81, Tyr82, His87, Ile91 and Phe99), many of them highly hydrophobic, show direct contacts (less than 4 Å) with the macrolide (Figure 4A). Hydrogen bonds between FK506 and the residues Asp37, Glu54, Ile56 and Tyr82 provide additional stabilization to the drug/enzyme complex.

Of special interest is the presence of a predominantly aromatic “cage”, formed by the side-chains of residues Tyr26, Phe46, Val55, Trp59 and Phe99, at the site where the pipercolinyl moiety of FK506 rests (Figure 4B). This cavity is also the binding site for the five-membered pyrrolidyl ring of 3-(3-pyridyl)-1-propyl(2S)-1-(3,3-dimethyl-1,2-dioxopentyl)-2-pyrrolidinecarboxylate (GPI1046) in the solution structure of the FKBP12/GPI1046 complex (Sich et al., 2000), and has been therefore assumed as the binding site for the prolyl moieties of FKBP12 substrates. Other features of the FKBP12/FK506 structure are (i) that the pipercolinyl-C8 carbonyl bond exhibits a *trans* conformation that does not resemble a twisted amide bond as had been proposed (Rosen et al., 1990) before the complex structure was solved, and (ii) the orientation of the methyl group C35 of the hemiacetal ring towards a hydrophobic cavity formed by the side-chains of residues Phe36, Tyr82, His87, Ile90 and Ile91, which may provide an explanation for the higher catalytic efficiency of this protein in substrates with large hydrophobic residues (i.e. leucine or phenylalanine) in the position before the proline.

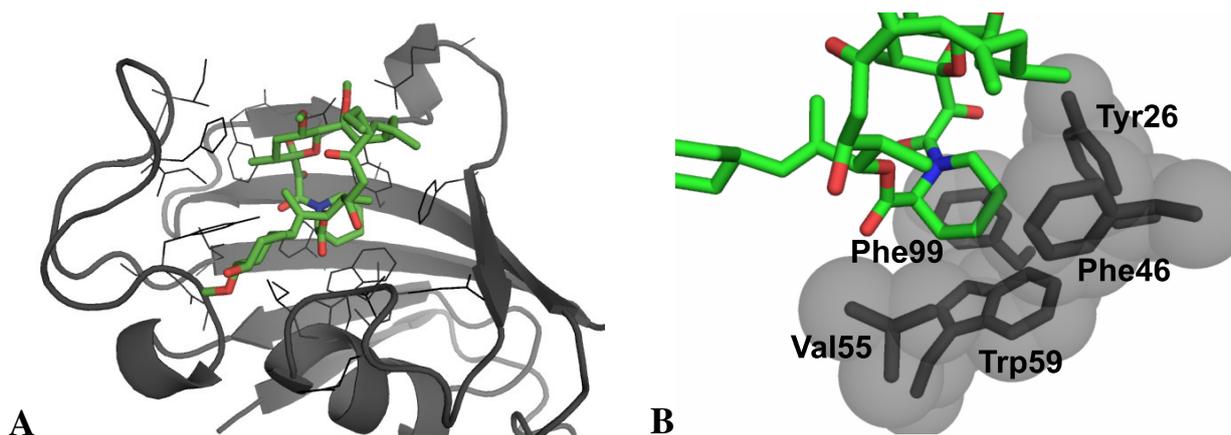

Figure 4. Graphic representations of the FKBP12/FK506 complex structure. (A) The FK506 molecule (represented as sticks colored by atom type) rests in a hydrophobic cavity located between the interior side of the β -sheet and the α -helix. The backbone of FKBP12 is represented as a gray ribbon and the side-chains of the protein residues interacting with the FK506 molecule as black lines. (B) Close-up of the pipercolinyl moiety of FK506 (sticks colored by atom type) and neighboring FKBP12 residues (gray sticks and spheres).

Although the structure of the FKBP12/FK506 complex provides some insight as to what might be the mechanism of catalysis in the FKBP12s, certain experimental findings, such as the low degree of conservation of the amino acid residues interacting with the FK506 molecule (Fanghanel and Fischer, 2004) as well as differences between peptide substrates and FK506 in the fluorescence quenching of the Trp59 ring that is located at the bottom of the binding cavity, raise some doubt about the hypothesis that the FKBP12/FK506 structure mimics the FKBP12/substrate complex (Park et al., 1992).

1.1.3.2. FKBP12s with TPR domains: FKBP51, FKBP52 and *A*tFKBP42

The human FKBP51 (FKBP54, gene name FKBP5) and FKBP52 (FKBP56, FKBP59, p59, gene name FKBP4) are two very similar FKBP12s containing TPR domains. Both present the same overall domain organization: two consecutive FKBP12 domains, followed by a TPR domain comprising three tetratricopeptide repeats (TPRs), each of which consists of two antiparallel α -helices (α 1 to α 6), plus an additional α -helix (α 7) that contains the calmodulin-binding motif and is structurally associated to the TPR domain. FKBP51 and FKBP52 are both involved, when bound to Hsp90 via their TPR domains, in the formation of high affinity steroid receptor complexes (Pratt et al., 1999). In both proteins, only the first FKBP12 domain, i.e. the one most similar to FKBP12, exhibits PPIase activity (Barent et al., 1998). The three-dimensional structures of FKBP51 and FKBP52 have been solved recently by X-ray crystallography (Sinars et al., 2003; Wu et al., 2004).

The FKBP42 from *Arabidopsis thaliana* (*AtFKBP42*) is another FKBP with a TPR domain of known three-dimensional structure. This protein presents a domain organization similar to that of FKBP51 and FKBP52, except for (i) the presence of only a single FKBP domain, which is inactive like the second domain of both human proteins, and (ii) the addition of a C-terminal membrane anchor. Its TPR domain interacts with *AtHsp90*, resembling the complex between the human proteins FKBP52 and Hsp90 (Kamphausen et al., 2002), while its FKBP domain can interact with the C-terminal nucleotide-binding domains (NBDs) of the plasma membrane-localized ATP-binding cassette (ABC) transporters *AtPGP1* and *AtPGP19* (Geisler et al., 2003). The crystal structures of (i) the FKBP domain (Weiergraber et al., 2005) and (ii) a construct comprising the FKBP and TPR domains (Granzin et al., 2006) of *AtFKBP42* were recently published.

The FKBP activity of the first FKBP domain of both FKBP51 and FKBP52 may be explained by their high degree of sequence similarity to FKBP12 (Figure 5A). In particular the residues involved in the interaction with the ligand FK506 are mostly conserved. The active sites of these domains are therefore structurally very similar to that of FKBP12 (Figure 5B).

On the other hand, the sequence of the FKBP domain of *AtFKBP42* displays some notable differences with respect to that of FKBP12 (Figure 5D). Especially, amino acid insertions in the loops $\beta 5-\alpha 1$ and $\beta 2-\beta 3$ lead to significant differences between the hydrophobic cleft of *AtFKBP42* and the active site of FKBP12 (Figure 5C). The insertion of one residue in the loop $\beta 5-\alpha 1$ produces a change in the topology of this loop, which partly protrudes into the binding pocket. More precisely, the segment Lys103-Leu106 would overlap with the FK506 molecule of the FKBP12/FK506 complex. Moreover, some hydrogen bonds between FK506 and residues in the $\beta 5-\alpha 1$ loop of FKBP12 cannot be formed in *AtFKBP42*. In addition, the insertion of two residues in the loop $\beta 2-\beta 3$ leads to an extension of this loop above the binding pocket. Consequently, the residues Phe140 and Pro141, while largely not overlapping with the FK506 molecule, close the entrance portal to the hydrophobic cleft of the FKBP domain of *AtFKBP42*. All these differences may explain the lack of FKBP activity reported for the FKBP domain of *AtFKBP42* (Weiergraber et al., 2005).

The TPR domains of FKBP51, FKBP52 and *AtFKBP42* display very similar conformations (Figure 6A), as indicated by backbone root-mean-square deviations (RMSDs) of 1.17 Å, 1.04 Å and 0.53 Å (only considering the three TPR motifs) between the superposed structure pairs *AtFKBP42*-FKBP51, *AtFKBP42*-FKBP52 and FKBP51-FKBP52, respectively. The helix $\alpha 7$ of FKBP52, however, is shifted by more than 30° from the Hsp90 binding surface relative to

FKBP51. These different orientations of helix $\alpha 7$ have been attributed to the presence of Ile400 in the $\alpha 7$ helix of FKBP52 (instead of Ala398 in FKBP51), which would otherwise collide with the phenyl group of Phe369 (Wu et al., 2004).

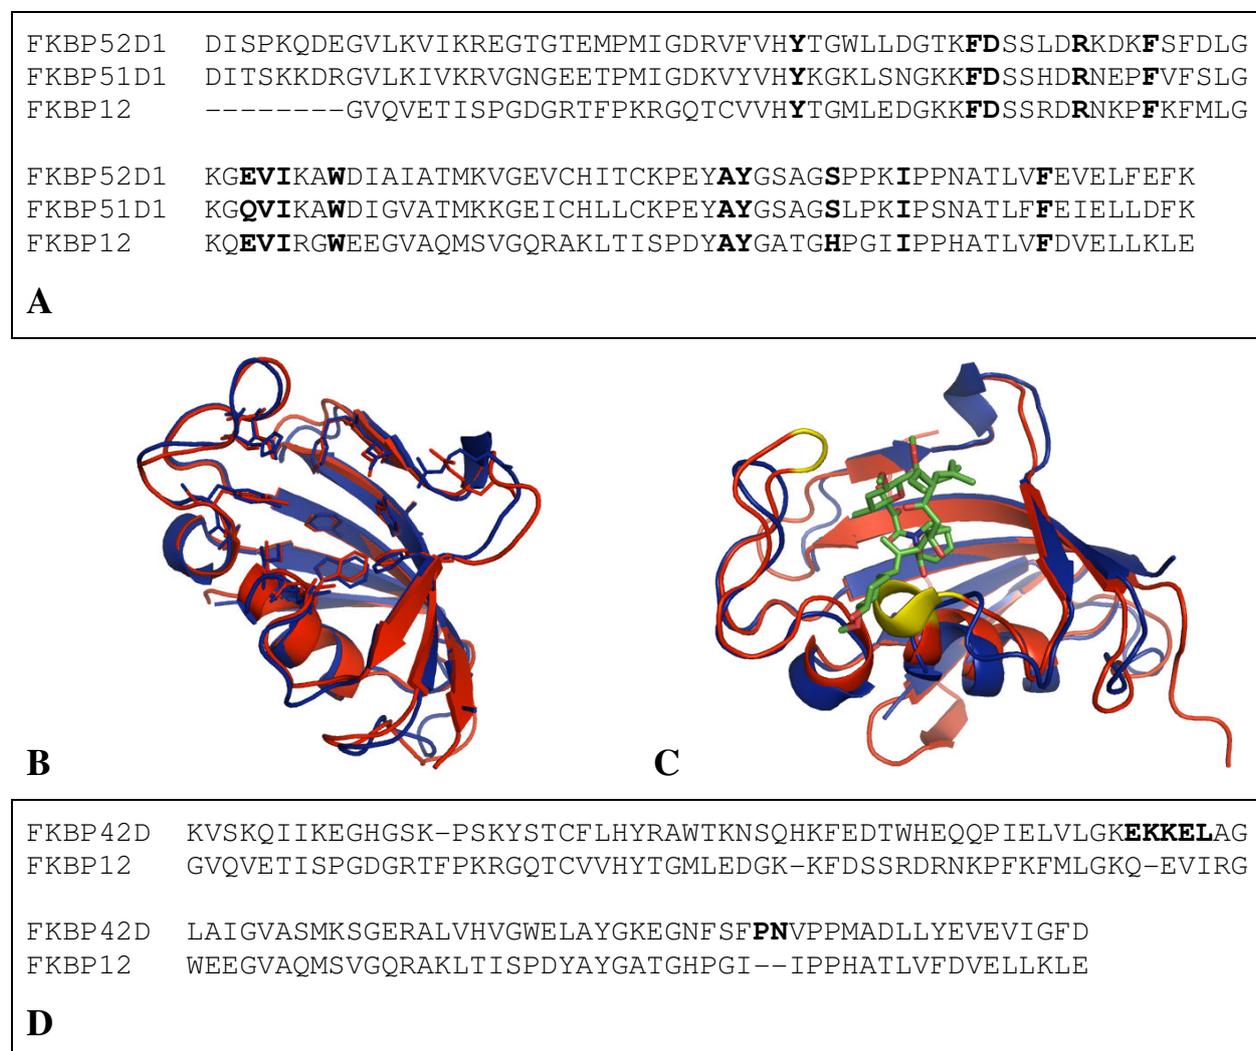

Figure 5. (A) Sequence alignment of the first FKBP domain of both FKBP52 and FKBP51 with FKBP12. The residues involved in the interaction with FK506 in the FKBP12/FK506 complex are highlighted in bold. (B) Superposition of the first FKBP domain of FKBP52 (red) with FKBP12 (blue). The side-chains of residues interacting with FK506 are shown as lines. (C) Superposition of the FKBP domain of *At*FKBP42 (red) with the FKBP12/FK506 complex (blue). The FK506 molecule is represented as stick model colored by atom type. Parts of the loops $\beta 2$ - $\beta 3$ and $\beta 5$ - $\alpha 1$, which were identified as responsible for the lack of FKBP activity of *At*FKBP42, are highlighted in yellow. (D) Sequence alignment of the FKBP domain of *At*FKBP42 with FKBP12. The segment Glu102-Leu106 in the loop $\beta 5$ - $\alpha 1$, and the insertion Pro141-Asn142 in the loop $\beta 2$ - $\beta 3$ of *At*FKBP42 are highlighted in bold.

In all three structures the TPR domain adopts a different orientation relative to the preceding FKBP domain (Figure 6B). These arrangements are partially stabilized by polar and hydrophobic interactions. These interactions, however, are likely to occur as a result of crystal packing (Wu et al., 2004; Granzin et al., 2006), considering that the FKBP and TPR domains have been

implicated in a variety of biological processes involving numerous interaction partners that may not be compatible with a fixed domain arrangement.

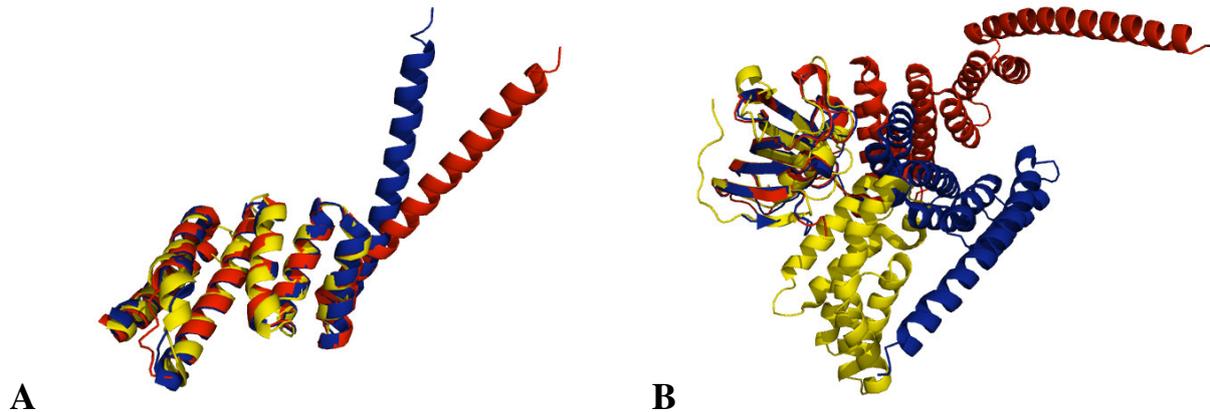

Figure 6. Superpositions of different regions of the FKBP51, FKBP52 and *At*FKBP42 structures. **(A)** The TPR domains of FKBP51 (blue), FKBP52 (red) and *At*FKBP42 (yellow) are superposed, with the exception of the helix $\alpha 7$. **(B)** The second FKBP domain of both, FKBP51 (blue) and FKBP52 (red), as well as the FKBP domain of *At*FKBP42 (yellow) are superposed, while the TPR domains display different orientations.

1.2. Calcium and calcium-binding proteins

The calcium ion (Ca^{2+}) is essential for the physiology of higher organisms, as it is involved in the regulation of diverse cellular processes such as cell proliferation, development, motility, secretion, muscle contraction, as well as in learning and memory (Carafoli, 2002; Berridge et al., 2000; Evenas et al., 1998). In many organisms, the majority of Ca^{2+} occurs as calcium phosphate in the exo- or endoskeletons, which serve as structural scaffolds and also buffer the Ca^{2+} levels within extracellular fluids at 10^{-3} M. The resting concentration of intracellular free Ca^{2+} ($\sim 10^{-7}$ M) is 10^4 times lower than that outside the cells, providing the potential for its import into the cells, where it acts as a universal second messenger.

The intracellular concentration of Ca^{2+} can be affected by a variety of processes. Thus, various stimuli, such as changes in membrane polarization or the binding of small ligands to membrane receptors, can lead to the influx into the cytosol of either extracellular Ca^{2+} ions via plasma-membrane Ca^{2+} channels or Ca^{2+} ions from intracellular organelles, producing an up to 100-fold increase in the cytosolic Ca^{2+} concentration (Bootman et al., 2001). As soon as the concentration of Ca^{2+} ions increases, the combined action of Ca^{2+} -binding proteins, Ca^{2+} pumps and $\text{Na}^+/\text{Ca}^{2+}$ exchangers sequesters these additional ions either to intracellular storage sites or outside the cell. A complex network of regulatory mechanisms affects the actions of the key proteins involved in the transport of Ca^{2+} ions, leading to oscillations of defined amplitude, frequency and location in

the Ca^{2+} concentration (Berridge, 1990; Meyer and Stryer, 1991). This transient behavior of the intracellular Ca^{2+} concentration itself can activate or regulate a variety of cellular processes, depending on its entry route into the cell, local site of action and pattern of modulation (Berridge et al., 1998; Berridge et al., 2000; Carafoli et al., 2001).

The information encoded in transient intracellular Ca^{2+} signals is deciphered by a number of Ca^{2+} -binding proteins, which convert these signals into a variety of biochemical and cellular changes. Several hundred of these proteins have been identified, most of them sharing a common Ca^{2+} -binding motif: the EF-hand (Ikura, 1996; Nelson and Chazin, 1998; Lewit-Bentley and Rety, 2000). This motif consists of about 30 amino acids organized in a helix-loop-helix topology, where the two helices are arranged similar to the extended thumb and index finger of a hand. In most Ca^{2+} -binding proteins, two EF-hand motifs are forming an EF-hand pair, which consists of a twisted four-helix bundle (Kretsinger, 1996; Chazin, 1995). Two different modes of response to the Ca^{2+} signal are known for these proteins. One group acts as Ca^{2+} buffers or transporters, like parvalbumin and calbindin, and does not show significant conformational changes upon Ca^{2+} binding. The other group, the so-called Ca^{2+} sensors, undergo a Ca^{2+} -induced conformational change (Ikura, 1996; Yap et al., 1999), allowing these proteins to act as Ca^{2+} switches that - once they are activated - regulate downstream effectors (Braunewell, 2005; Chin and Means, 2000; Carafoli et al., 2001).

1.2.1. Calmodulin

Calmodulin (CaM) is the prototypic Ca^{2+} sensor and has been studied extensively. It is a relatively small protein (148 amino acids and 16.8 kDa in vertebrates) that is highly conserved, water soluble and omnipresent in the cytosol of all eukaryotic cells, where it participates in signalling pathways that regulate many crucial cellular processes such as growth, proliferation and movement (Cohen and Klee, 1988; Eldik and Waterson, 1998). It constitutes at least 0.1% of the total protein content in the cell (10^{-6} to 10^{-5} M) and can be expressed at higher levels in rapidly growing cells, especially in those undergoing division and cell differentiation (Chin and Means, 2000). The importance of this protein for mammalian cell survival is also reflected by the presence of multiple CaM genes (e.g. three in both humans and rodents) at separate chromosomes (Toutenhoofd and Strehler, 2000)

CaM comprises four EF-hand motifs. The first two are combined to form a globular N-terminal domain, separated by a short flexible linker from a highly homologous (48% sequence identity and 75% sequence homology) C-terminal domain, which also contains two EF-hand motifs. Its

Ca^{2+} affinities ($K_D \sim 5 \times 10^{-7}$ M for the C-terminal domain and $\sim 5 \times 10^{-6}$ M for the N-terminal domain) (Gilli et al., 1998; Potter et al., 1983; Ogawa et al., 1984) fall within the range of Ca^{2+} concentrations exhibited by most cells (10^{-7} M to 10^{-5} M), thus allowing this protein to act as an intrinsic Ca^{2+} sensor. Moreover, the difference of about one order of magnitude in the Ca^{2+} affinities between the CaM C- and N-terminal domains provides an additional capability to discriminate the Ca^{2+} signals.

The structures of apo- and holo-calmodulin have been studied extensively by NMR spectroscopy and X-ray crystallography. Consequently, several structures of apo-CaM (Kuboniwa et al., 1995; Finn et al., 1995; Zhang et al., 1995) and holo-CaM (Babu et al., 1985; Babu et al., 1988; Chattopadhyaya et al., 1992; Chou et al., 2001) have been published, providing a deep insight into the biological properties of this protein.

Both apo- and holo-CaM fold into two small, highly similar globular domains connected by a central linker (Figure 7). In holo-CaM, this linker was found to be α -helical in the crystalline state (Babu et al., 1985). NMR relaxation studies that were carried out with both CaM forms, however, demonstrated that this central linker is non-helical and highly flexible in solution (Barbato et al., 1992; Tjandra et al., 1995). Consequently, the N- and C-terminal domains of CaM do not adopt a defined orientation relative to each other in solution. This property is fundamental for the activity of CaM, as it allows its two domains to adopt different relative orientations in order to interact with diverse binding partners.

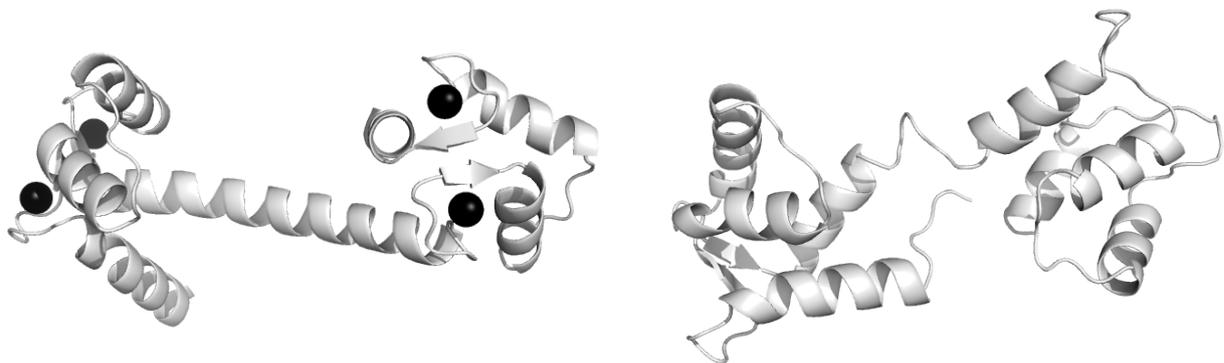

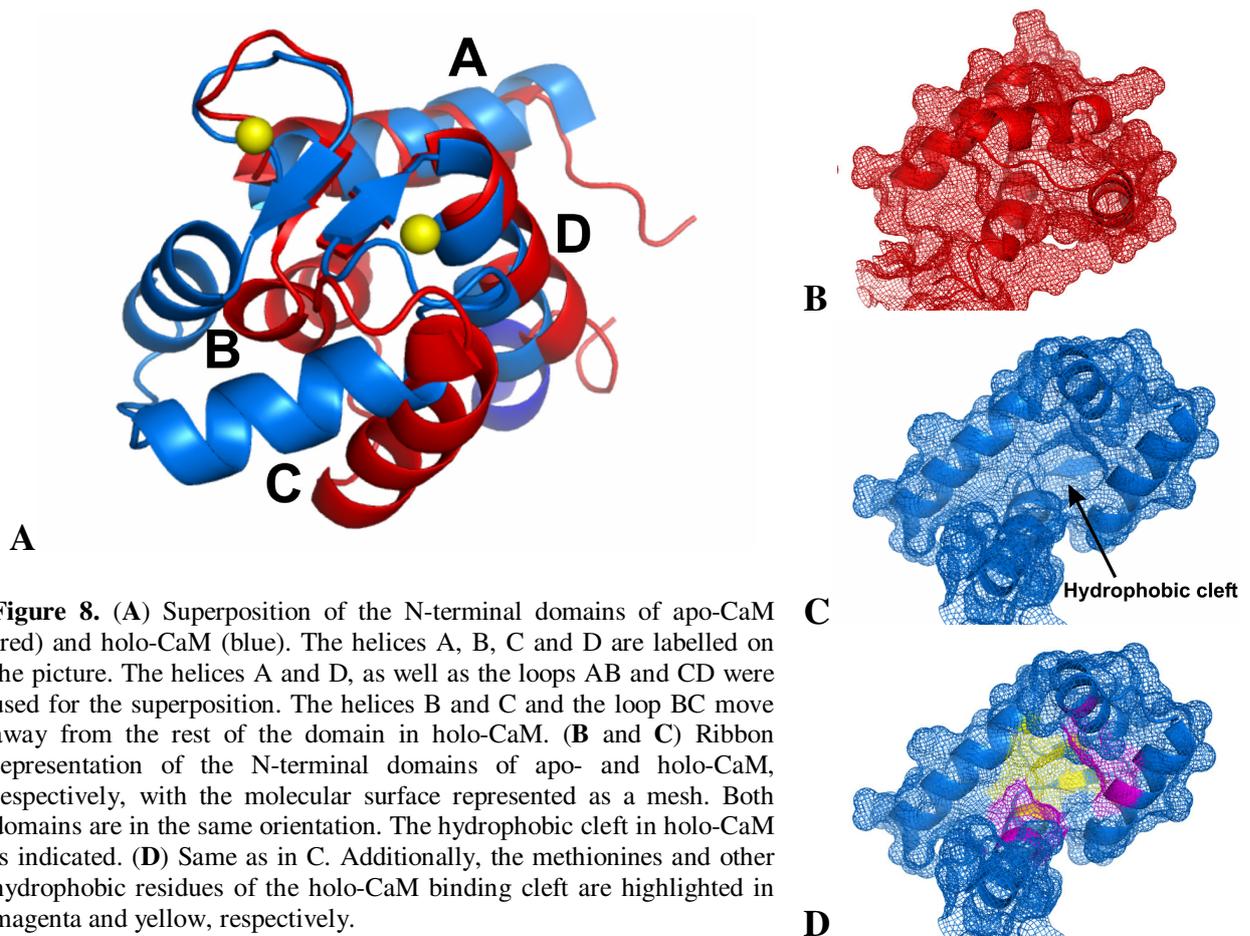

Figure 7. Overall structures of holo- (**left**) and apo-CaM (**right**). The Ca^{2+} ions in holo-CaM are shown as black spheres.

Each CaM domain contains two helix-loop-helix EF-hand motifs, linked by a short and slightly distorted two-stranded antiparallel β -sheet. The four helices of each CaM domain (i.e. A, B, C and D in the N-terminal as well as E, F, G and H in the C-terminal domain) adopt different relative orientations in apo- and holo-CaM (Figure 8A). Thus, in apo-CaM they are tightly packed, adopting nearly antiparallel orientations as indicated by the relative angles between the

helix pairs A-B (138°), C-D (130°), E-F (131°) and G-H (133°) (Figure 8B). Upon Ca^{2+} binding these helices rearrange, adopting perpendicular orientations in holo-CaM as indicated by the interhelical angles A-B (87°), C-D (113°), E-F (84°) and G-H (96°). This gives rise to methionine-rich, highly hydrophobic clefts in holo-CaM (Figure 8C and D), which are responsible for the binding of numerous target proteins. Moreover, the high flexibility and polarizability of methionine side-chains (Gellman, 1991) confers holo-CaM an additional ability to adapt to different target molecules (Zhang et al., 1994; Zhang and Vogel, 1994).

1.2.2. Calmodulin binding to target proteins

Calmodulin interacts in cells with a large number of target proteins, which are involved in a variety of cellular processes as diverse as muscle contraction, gene regulation, fertilization, cell proliferation, vesicular fusion and apoptosis (Cohen and Klee, 1988; Eldik and Waterson, 1998). Both, apo- and holo-CaM are able to interact with a large body of proteins (Jurado et al., 1999; Yamniuk and Vogel, 2004; Vetter and Leclerc, 2003). Most of these interactions lead to the activation of the target proteins, whereas others can modulate the action of CaM, for example

regulating its cellular localization (Chin and Means, 2000). Several consensus sequences mediating these interactions have been identified in CaM target proteins (Rhoads and Friedberg, 1997).

The most frequent CaM-binding domains are relatively short polypeptide chains of about 15-30 residues, which do not share a high homology but all have in common the tendency to form a basic, amphiphilic α -helix (Crivici and Ikura, 1995; Rhoads and Friedberg, 1997). They often partially overlap with autoinhibitory domains, as for example in CaM kinase kinase (CaMKK). Furthermore, many of them are close to regulatory phosphorylation sites (e.g. CaM kinase II) or to protein-protein or protein-membrane interaction domains (e.g. MARCKS protein) (Ishida and Vogel, 2006).

Among these numerous target proteins, the family of CaM-dependent serine/threonine kinases is the one best characterized with respect to their structural and functional CaM interaction mechanisms. These proteins are autoinhibited in the absence of Ca^{2+} and CaM, but they become active upon holo-CaM binding to their CaM-binding domains, which removes the autoinhibitory domain from the catalytic site of these enzymes. This activation mechanism also applies to a variety of other enzymes, such as the cerebellar nitric oxide synthase and the plasma membrane Ca^{2+} pump.

The interaction of holo-CaM with all these CaM-binding domains takes place in a similar manner, as revealed by several NMR and X-ray structures of holo-CaM with peptides corresponding to CaM-binding domains (Vetter and Leclerc, 2003; Yamniuk and Vogel, 2004; Ishida and Vogel, 2006). A common feature of all these peptides, in addition to the formation of a basic, amphiphilic α -helix when bound to holo-CaM, is the presence of regularly spaced hydrophobic residues (i.e. Trp, Phe, Ile, Leu or Val), which act as anchors to the hydrophobic cleft of the holo-CaM domains. Most of these peptides fall into one of three groups of CaM-target sequences (i.e. 1-10, 1-14 and 1-16) which are distinguished by the spacing of the two outer hydrophobic residues. The presence of additional hydrophobic amino acids in the middle of these sequences led to the definition of subgroups of CaM-binding motifs (i.e. 1-8-14, 1-5-8-14 and 1-5-10) (Rhoads and Friedberg, 1997). It is important to note, however, that many protein sequences that show no homology to these motifs can also bind CaM.

The typical features of most of the holo-CaM/target-peptide complexes are nicely exemplified in the structure of holo-CaM in complex with the CaM-binding domain from smooth muscle myosin light chain kinase (smMLCK) (Meador et al., 1992), which presents a 1-8-14 CaM-

binding motif. In this structure, the N- and C-terminal domains of CaM wrap around a helical peptide to form a globular complex (Figure 9A). The hydrophobic side-chains of Trp800 and Leu813 serve to anchor the N- and C-terminal ends of the peptide in an antiparallel arrangement to the C- and N-terminal domains of CaM, respectively. The predominantly hydrophobic interactions are further stabilized by salt-bridge formation between acidic side-chains from CaM and basic peptide residues. Interestingly, the conformation of the individual CaM domains remains almost unaffected by the complex formation, as revealed by the essentially unchanged backbone structure of both CaM domains.

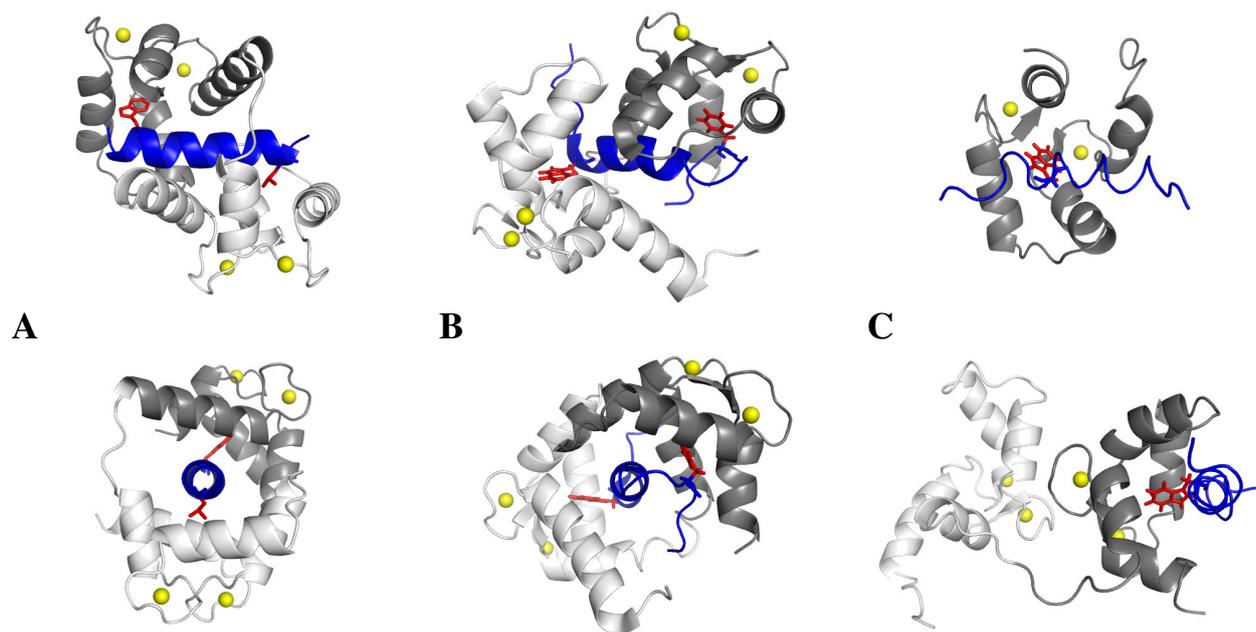

Figure 9. Comparison of the structures of holo-CaM in complex with peptides derived from the CaM-binding domains of (A) smMLCK (PDB ID code 1CDL) (B) CaMKK (PDB ID code 1CKK) and (C) a truncated CaM-binding domain (C20W) from the plasma membrane Ca^{2+} pump (PDB ID code 1CFF). The N-terminal and C-terminal domains of CaM are shown in white and gray, respectively, while the Ca^{2+} atoms are shown as yellow spheres. The CaM-binding domains are represented in blue and the hydrophobic anchors (Trp800 and Leu813 in A, Trp444 and Phe459 in B, and Trp8 in C) as red stick models. In the upper panel, the CaM-binding domains are oriented with the N-terminus on the left side, while in the lower panels the C-terminus is in front.

Significant alterations from this structure are displayed by the complexes with peptides from the auto-inhibitory domains of CaM-dependent kinase kinase (CaMKK) (Osawa et al., 1999) and the plasma membrane Ca^{2+} pump (C20W peptide) (Elshor et al., 1999). Thus, the peptide from CaMKK (Figure 9B) it is (i) bound in an “inverted” parallel orientation and (ii) only partially helical, forming an additional β -hairpin like loop, whereas the peptide from the plasma membrane Ca^{2+} pump is only bound to the C-terminal CaM domain (Figure 9C). These structures indicate the existence of a high degree of variability in the CaM-target peptide binding modes.

New activation mechanisms of CaM-target proteins have been revealed by the elucidation of the crystal structures of CaM in complex with the exotoxin edema factor from *Bacillus anthracis* (Drum et al., 2002) and a fragment from the Ca²⁺-activated K⁺ channel (Schumacher et al., 2001). These structures differ drastically from the CaM complexes with small peptides, thus providing more insight in the interactions of CaM with its target molecules.

The small conductance Ca²⁺-activated K⁺ channel (SK channel) consists of four membrane-spanning α -subunits and is gated by the intracellular Ca²⁺ concentration (Xia et al., 1998). The C-terminal cytosolic region of each α -subunit features one CaM molecule bound constitutively via a domain that shares no similarities with other CaM-binding domains and is not Ca²⁺ dependent. The structure of CaM in complex with a 96-residue fragment corresponding to this C-terminal cytosolic portion of the K⁺-channel (Figure 10A) was the first solved structure of CaM bound to a large protein fragment and thus provides interesting insight into the Ca²⁺-mediated activation of this channel. The CaM-binding domain of the K⁺-channel consists of two long antiparallel α -helices, $\alpha 1$ (residues 413-440) and $\alpha 2$ (residues 446-489), connected by a short loop (residues 441-445). Its complex with CaM is a symmetric tetramer, consistent of two molecules of each protein. The central part of the structure is a dimer of two CaM-binding domains that are connected via a side-by-side antiparallel interaction of their helices $\alpha 2$ and $\alpha 2'$. Two CaM molecules are bound each to one edge of the central dimer, interacting simultaneously with three helices of the dimer (i.e. $\alpha 1$, $\alpha 2$ and $\alpha 2'$) and covering over 80% of the dimer surface area. Consequently, CaM adopts an almost extended conformation. Remarkably, the C-terminal domain of CaM, which is bound to the helix $\alpha 1$, is free of Ca²⁺ and adopts the semi-open conformation, probably resembling the Ca²⁺-independent interaction of CaM with IQ-motifs, whereas the N-terminal CaM domain is Ca²⁺ bound and displays an open conformation, binding helix $\alpha 2'$ from the second CaM-binding site in a similar manner as in most of the CaM/peptide complexes. The regulation of the SK channel by Ca²⁺ and CaM can be summarized as follows: one CaM molecule is bound constitutively via its C-terminal domain to helix $\alpha 1$ of the cytosolic domain of each SK channel α -subunit. Once the Ca²⁺ concentration increases, the Ca²⁺-bound N-terminal CaM domain induces the dimerization of the cytosolic domains of two α -subunits, which causes the SK channel to open.

The structure of the CaM complex with the C-terminal fragment (residues 191-280) of the exotoxin edema factor from *Bacillus anthracis* (Figure 10B) is the first example where CaM was successfully crystallized together with a catalytically functional target. Moreover, comparison of the structures with and without CaM, as well as with the substrate analogue 3'-dATP, provided detailed information about the activation mechanism. The edema factor is a soluble adenylyl

cyclase that consists of three globular domains, referred to as CA, CB and helical domain, and three smaller parts (switch-A, -B and -C), which undergo large conformational changes in response to CaM binding. In the complex, CaM displays an extended conformation and is inserted between the CA and helical domains, separating the helical domain from the main structure. The C-terminal CaM domain is Ca²⁺-bound and adopts an open conformation, thus binding the helical switch-A, which is close to the CA domain of the edema factor. On the other hand, the tight interaction of the helices A and B from the N-terminal CaM domain with the CB domain of the edema factor prevents the rearrangement of these helices, which is required for Ca²⁺-binding. Thus, the N-terminal CaM domain remains free of Ca²⁺, displaying a closed conformation similar to that of apo-CaM, which is remarkable considering that the complex was crystallized under excess of Ca²⁺. The structural rearrangements produced by CaM binding lead to the formation of the active site in a region that is solvent exposed in the CaM-free state. This activation mechanism has therefore been referred to as “active-site remodeling” (Hoeflich and Ikura, 2002).

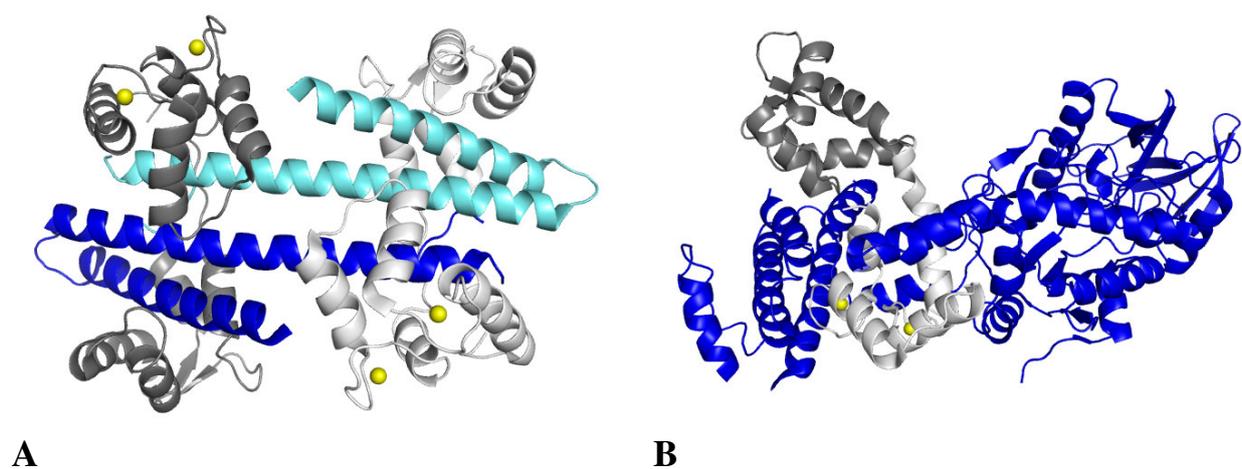

Figure 10. Structures of CaM in complex with (A) rat Ca²⁺-activated K⁺ channel (PDB ID code 1G4Y) and (B) anthrax adenylyl cyclase (PDB ID code 1K93). In (A), the two CaM molecules are represented in white or gray and the two peptide molecules from the Ca²⁺-activated K⁺ channel in blue or cyan. In (B), the N- and C-terminal domains of CaM are shown in white and gray, respectively, while the anthrax adenylyl cyclase is shown in blue. Ca²⁺ ions, bound to the N-terminal domain of CaM in (A) and to the C-terminal domain of CaM in (B), are shown as yellow spheres.

1.3. Objectives

The human FKBP38 displays a unique property among PPIases, as its FKBP activity is regulated by calmodulin in combination with Ca^{2+} . Moreover, it has been demonstrated that this protein plays an important role in apoptotic pathways. Therefore, the structural characterization of FKBP38, especially of its catalytic domain, as well as the study of the interactions between FKBP38 and CaM, are research topics of particular interest.

The first objective of this thesis is the structural elucidation of the catalytic domain of FKBP38 using high-resolution NMR spectroscopy. No previous work had been done in this direction. Therefore, all the usual stages of structure determination by NMR must be performed: (i) protein cloning, expression and purification, (ii) protein isotope labelling, (iii) complete resonance assignment and, (iv) structure calculation and refinement.

The second objective of this work is the characterization of the interactions between FKBP38 and CaM. NMR chemical shift perturbation mapping has been selected as the method of choice to study these relatively weak interactions. As chemical shift assignments of the two CaM forms under the experimental conditions used in this study have not been previously reported, the first goal is to achieve the backbone amide resonance assignment of both apo- and holo-CaM under these conditions. Next, the NMR chemical shift perturbations study of the interactions of apo- and holo-CaM with the FKBP domain of FKBP38 should be carry out. In addition, the interactions of holo-CaM with the putative CaM-binding-site of FKBP38 should be examined by the same procedure. The information obtained from these chemical shift perturbation measurements can then be used to elucidate the structures of the corresponding complexes. This ought to provide some insight into the activation of FKBP38 by CaM. Furthermore, a model of the overall complex between FKBP38 and CaM shall be derived.

2. Materials and Methods

2.1. Materials

2.1.1. Chemicals and materials

All chemicals used had at least the purity grade “pro analysii”.

Chemical	Distributor
Acetic acid	Merck (Darmstadt)
Agar	AppliChem (Darmstadt)
Agarose	Roth (Karlsruhe)
Ammonium sulfate	Merck (Darmstadt)
5-Bromo-4-chloro-3-indolyl- β -D-galactoside	Roth (Karlsruhe)
Bromophenolblue	Serva (Heidelberg)
Calcium chloride	Merck (Darmstadt)
Chloramphenicol	Sigma (Deisenhofen)
Coomassie Brilliant Blue	Serva (Heidelberg)
Crystal Screen TM	Hampton Research Corp. (Aliso Viejo, USA)
Crystal Screen 2 TM	Hampton Research Corp. (Aliso Viejo, USA)
Deuterium oxide (99.9%)	VEB Berlin Chemie (Berlin)
2,2-Dimethyl-2-silapentane-5-sulfonate	Cambridge Isotope Laboratories (Andover, USA)
dNTP	PeqLab (Erlangen)
EDTA	Roth (Karlsruhe)
EGTA	Sigma (Deisenhofen)
Ethanol	Fluka (Neu Ulm)
Ethidium bromide	Roth (Karlsruhe)
Glycerol	Roth (Karlsruhe)
Glycine	Fluka (Neu Ulm)
HEPES	AppliChem (Darmstadt)
Hydrochloric acid	Merck (Darmstadt)
IPTG	AppliChem (Darmstadt)
JBScreen Classic 1-4	Jena Bioscience (Jena)

Kanamycin	AppliChem (Darmstadt)
Magnesium chloride	Merck (Darmstadt)
Magnesium sulfate	Invitrogen (Karlsruhe)
MES	Serva (Heidelberg)
¹⁵ N-enriched “rich growth OD2” medium	Silantes (München)
PEG4000	Serva (Heidelberg)
Peptone	Fluka (Buchs, Switzerland)
Phosphoric acid	Laborchemie Apolda (Apolda)
Potassium chloride	Merck (Darmstadt)
Regenerated cellulose tubular membrane	Roth (Karlsruhe)
SDS	Serva (Heidelberg)
Sodium azide	Merck (Darmstadt)
Sodium chloride	Merck (Darmstadt)
Sodium hydroxide	Merck (Darmstadt)
Tetracycline	Sigma (Deisenhofen)
TRIS	Serva (Heidelberg)
Vivaspin® (5 kDa cut-off)	Sartorius (Göttingen)
Yeast extract	Serva (Heidelberg)

2.1.2. Enzymes

Restriction endonucleases	New England Biolabs (Beverly, USA)
<i>Pfx</i> DNA-polymerase	Invitrogen (Karlsruhe)
<i>Taq</i> DNA-polymerase	New England Biolabs (Beverly, USA)
<i>T4</i> DNA-ligase	New England Biolabs (Beverly, USA)

2.1.3. Plasmids and templates

pSTBlue-1	Novagen (Madison, USA)
pET28a	Novagen (Madison, USA)
Template for FKBP38	Provided by Dr. Frank Edlich (MPG, Halle)

2.1.4. PCR primers

FKBP38 ³⁵⁻¹⁵³ -5'	5'-GACTTCATGAGAAGAGTGGCTGGACATTCTG-3'
FKBP38 ³⁵⁻¹⁵³ -3'	5'-GACTAAGCTTTCACTCCAGGTCAGGCCCG-3'

2.1.5. *Escherichia coli* cells

BL21(DE3) Rosetta	Novagen (Madison, USA)
DH5 α	Invitrogen (Karlsruhe)

2.1.6. Proteins and peptides

Calmodulin	Provided by Dr. Frank Edlich (MPG, Halle)
¹⁵ N-labelled Calmodulin	Provided by Dr. Frank Edlich (MPG, Halle)
C-terminal Calmodulin	Provided by Dr. Frank Edlich (MPG, Halle)
FKBP38 ²⁹⁰⁻³¹³	Provided by Dr. Günther Jahreis (MPG, Halle)
Partially ¹⁵ N-labelled FKBP38 ²⁹⁰⁻³¹³	Provided by Dr. Günther Jahreis (MPG, Halle)

2.1.7. Chromatography columns

Fractogel EMD-DEAE-650(M)	Merck (Whitehouse Station, USA)
HiLoad 16/60 Superdex 200 pg column	GE Healthcare (Waukesha, USA)

2.1.8. Standards

100 bp DNA standard	New England Biolabs (Beverly, USA)
1 kb DNA standard	New England Biolabs (Beverly, USA)
10 kDa protein standard	Fermentas (St. Leon-Rot)

2.1.9. Kits

<i>High Pure</i> [®] PCR product purification	Roche Diagnostics (Mannheim)
<i>Perfectly Blunt cloning kit</i>	Novagen (Madison, USA)
<i>QIAquick</i> [®] Gel extraction kit	Qiagen (Hilde)
<i>QIAprep</i> [®] Spin miniprep kit	Qiagen (Hilde)

The kits were used according to the recommendations of the manufacturers.

2.1.10. Buffers, media and stock solutions

Application buffer for agarose gel: 1x TAE buffer, 20% glycerol, 5 mM bromophenol blue.

SDS-PAGE buffer: 25 mM TRIS/HCl (pH 8.8), 150 mM glycine, 0.01% (w/v) SDS.

50 x TAE buffer (1l): 40 mM TRIS/HCl (pH 8.0), 57.1 ml acetic acid, 0.05 M EDTA, H₂O.

LB medium: 10 g/l peptone, 5 g/l yeast extract, 5 g/l NaCl (pH 7.5).

Stock solutions (all stored at -20 °C and applied in a volume ratio 1:1000):

IPTG: 238 mg/ml (1 M) in H₂O
Chloramphenicol: 34 mg/ml in ethanol
Kanamycin: 50 mg/ml in H₂O
Tetracyclin: 5 mg/ml in ethanol (applied in a volume ratio 1:500)

2.1.11. Equipment

Avance-700 NMR spectrometer	Bruker (Rheinstetten)
Chromatography system	Amersham Pharmacia (Uppsala, Sweden)
DRX500 NMR spectrometer	Bruker (Rheinstetten)
Electrophoresis and blot apparatus	Biometra (Göttingen)
French [®] Press	SLM Aminco (Rochester, USA)
GeneQuant II spectrophotometer	Amersham Pharmacia (Uppsala, Sweden)
Heraeus Biofuge 22R centrifuge	Kendro (Hanau)
Heraeus Biofuge Stratos centrifuge	Kendro (Hanau)
HP-8453 diode array spectrophotometer	Hewlett Packard (Böblingen)
InoLab pH 720 pH-meter	WTW (Weilheim)
Optima [®] LE-80 K ultracentrifuge	Beckman Coulter (Krefeld)
PCR thermocycler	Biometra (Göttingen)
Sorval M120GX ultracentrifuge	Kendro (Hanau)

2.2. Methods

2.2.1. Molecular biology methods

2.2.1.1. Polymerase chain reaction

The polymerase chain reaction (PCR) technique (Mullis and Faloona 1987; Saiki et al. 1988) was used for the preparation and amplification of DNA for subcloning of recombinant human FKBP38³⁵⁻¹⁵³.

The 5' PCR primer was designed with a splice site for the restriction endonuclease *Bsp*HI, and the 3' primer with a stop codon and a splice site for the restriction endonuclease *Hind*III.

Several PCR trials were made with two different DNA-polymerases (*Taq* and *Pfx*) as well as different concentrations of MgSO₄ and polymerase enhancer. The best results were obtained with the protocol shown in Table 1.

Table 1. Description of the PCR experiment displaying the best results.

PCR solution		PCR program
<i>Pfx</i> DNA-polymerase (1U/ μ l)	0.5 μ l	1) 3 min 95 °C
<i>Pfx</i> polymerase buffer (1U/ μ l)	5 μ l	2) 20 sec 95 °C
Primer 3' (100 pmol/ μ l)	0.5 μ l	3) 30 sec 54 °C
Primer 5' (100 pmol/ μ l)	0.5 μ l	4) 1 min 72 °C
DNA-template (150 μ g/ml)	0.5 μ l	5) 5 min 72 °C
dNTP-mix (10 mM)	0.5 μ l	
MgSO ₄ (50 mM)	2 μ l	
Distilled water	40.5 μ l	

The DNA thus obtained was subsequently verified by agarose gel electrophoresis, restriction analysis and DNA sequencing.

2.2.1.2. Agarose gel electrophoresis

The amplified DNA from the PCR was applied, together with 1/10 volume of application buffer, to a 1% (w/v) agarose gel containing 0.5 μ g ethidium bromide per ml of gel (Telford et al. 1977). The DNA was separated at 6-10 V/cm in 1 x TAE buffer. The DNA bands were detected with a UV lamp at 312 nm. Afterwards, the DNA was isolated with the *QIAquick*[®] kit.

2.2.1.3. DNA quantification

The DNA concentration was measured in 10 mm quartz cells with a GeneQuant II spectrophotometer working at 260 nm. An OD = 1.0 corresponds to 50 μ g/ml of double-stranded DNA.

2.2.1.4. Enzymatic modification of DNA

The purified DNA product was subcloned into a pSTBlue-1 vector, digested with *Bsp*HI/*Hind*III, and then ligated into a pET28a vector.

Ligation: 50-200 ng of the DNA fragment, 5-fold excess of the vector DNA, 1 U of T4 DNA ligase (0.5 μ l), and 1 μ l of 10 x T4 buffer were incubated in a total volume of 10 μ l at 25 °C for 30 minutes. The blind end ligation was carried out with the *Perfectly Blunt cloning* kit.

DNA splicing: 0.5-10 μ g of DNA, 1.5 U of each restriction enzyme (0.75 μ l), and 1 μ l of 10 x enzyme buffer were incubated in a total volume of 10 μ l at 37 °C for 3 hours.

2.2.1.5. Plasmid mini-preparation

5 ml of an overnight *E. coli* cell culture were centrifuged at 15.000 x g for 5 minutes. The resulting cell pellet was processed with the *QIAprep*[®] kit.

2.2.1.6. Transformation into competent *Escherichia coli* cells

0.1-20 µg of plasmid were added to 50 µl of competent cells. The cells were incubated in ice for 30 minutes, and afterwards submitted to a heat shock at 42 °C for 45 seconds. Next, 300 µl of LB medium were added and the cells were incubated at 37 °C for 1 hour. Finally, the entire cell solution was applied to an agar plate containing the adequate antibiotics for selection of the transformed cells and incubated overnight at 37 °C.

2.2.1.7. Culturing of *Escherichia coli* cells

The *Escherichia coli* (*E. coli*) cells were grown in LB medium (containing the adequate antibiotics for selection) at 37 °C and 220 rpm.

For the preparation of glycerol stocks, 700 µl of overnight cell culture were added to 300 µl of glycerol, frozen with liquid nitrogen, and stored at -80 °C.

2.2.2. Preparative methods

2.2.2.1. Overexpression tests

500 µl of overnight cell culture and the required amount of antibiotic were added to 5 ml of LB medium in a test tube. The cells were grown for 3 hours at 37 °C and 220 rpm before protein expression was induced with 50 µl of 0.1 M isopropyl-β-D-thiogalactoside (IPTG) and subsequent incubation for 4 hours under the same conditions. Afterwards, 1 ml of cell culture was centrifuged and the resulting bacterial pellet lysed by ultrasonication for 30 seconds in 25 mM TRIS buffer (pH 7.5). After centrifugation for 15 minutes at 15,000 x g, the protein content in the cell lysate was analyzed by SDS-PAGE.

2.2.2.2. Expression of recombinant FKBP38³⁵⁻¹⁵³

Recombinant expression of FKBP38³⁵⁻¹⁵³ in 6 l of LB medium at 37 °C was induced when OD₆₀₀ was ~ 0.8 by adding IPTG to a final concentration of 1 mM and subsequent incubation for another 4 hours. Next, cells were harvested by centrifugation for 15 minutes at 4 °C and 5,000 × g.

For ¹⁵N-labelling, the cells were grown and expressed in a fully ¹⁵N-enriched “rich growth OD2” medium according to the recommendations of the supplier.

2.2.2.3. Lysis of *Escherichia coli* cells

The bacterial pellet from a 6 l culture was resuspended in 200 ml lysis buffer (10 mM MES pH 6.0, 150 mM NaCl) and cracked three times in a French® press at 10,000 PSI. The supernatant was centrifuged for 45 minutes at 4 °C and 100,000 × g.

2.2.2.4. Purification of FKBP38³⁵⁻¹⁵³

The soluble cell lysate was applied to a Fractogel EMD DEAE-650 column, equilibrated with 10 mM MES buffer (pH 6.0, 150 mM NaCl). The protein was eluted from the DEAE-650 column with 1 M NaCl and the fractions were analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) as described in section 2.2.3.1. The fractions containing FKBP38³⁵⁻¹⁵³ were dialyzed against 10 mM HEPES buffer (pH 7.8, 1.5 mM MgCl₂, 150 mM KCl) and loaded on a HiLoad 16/60 Superdex 200 pg column according to the recommendations of the supplier. The protein fractions were analyzed by SDS-PAGE. The purified FKBP38³⁵⁻¹⁵³ was subsequently analyzed by MALDI-TOF mass spectrometry and N-terminal protein sequencing, thereby confirming the identity of the protein.

2.2.3. Analytical methods

2.2.3.1. SDS-PAGE

The proteins were separated according to size by means of SDS-PAGE. The discontinuous method of Laemmli (Laemmli, 1970) was applied for the separation in 15% (w/v) gels. The resolved protein bands were detected with Coomassie blue.

2.2.3.2. Protein quantification

The concentrations of purified proteins were determined by means of UV-VIS spectroscopy at 280 nm. The extinction coefficients for the Lambert-Beer equation were calculated according to the method of Gill and von Hippel (Gill and von Hippel, 1989) using the internet program ProtParam tool (www.expasy.ch).

2.2.3.3. Internet-based programs

The program *Webcutter2.0* was used for the analysis of the splice sites for restriction endonucleases. The properties of the PCR primers were calculated and analyzed with the program *Oligonucleotide Properties Calculator*. The search for homologue protein sequences was carried out with the corresponding *BLAST* program of the NCBI (Altschul et al., 1990). *ClustalW* (Thompson et al., 1994) was used for the comparison of protein sequences. A variety of protein properties (e.g. molecular weight, pI, extinction coefficients) were calculated with the ProtParam tool of the Expasy proteomics server (www.expasy.ch). Binding motifs for calmodulin were analyzed with the *Calmodulin Target Database*, accessible at <http://calcium.uhnres.utoronto.ca/ctdb>. Part of the three-dimensional structure analysis was carried out with the program Pymol (DeLano Scientific LLC, 2006) accessible at www.pymol.org.

2.2.4. NMR spectroscopy

2.2.4.1. Structural study of FKBP38³⁵⁻¹⁵³

2.2.4.1.1. Sample preparation

The NMR structural determination of FKBP38³⁵⁻¹⁵³ was carried out with samples consisting of either non-labelled or ¹⁵N-enriched FKBP38³⁵⁻¹⁵³ (1.3-1.4 mM) dissolved in 20 mM sodium phosphate buffer (pH 6.7, 0.05% (w/v) NaN₃, 5% (v/v) D₂O) at 298 K. Under these conditions, the protein was stable for about one week.

2.2.4.1.2. NMR experiments

All NMR data were collected with Avance-700 (University of Leipzig) and DRX500 spectrometers operating at 500.13 and 700.13 MHz proton resonance frequencies respectively. Both spectrometers were equipped with 5 mm inverse triple-resonance ($^1\text{H}/^{13}\text{C}/^{15}\text{N}$) probes with XYZ-gradient coils. Several homonuclear two-dimensional (2D) spectra ($^1\text{H}/^1\text{H}$ -TOCSY and $^1\text{H}/^1\text{H}$ -NOESY), as well as ^{15}N -edited multidimensional spectra (2D $^1\text{H}/^{15}\text{N}$ -HSQC, 2D $^1\text{H}/^{15}\text{N}$ -HTQC, 3D $^1\text{H}/^{15}\text{N}$ -TOCSY-HSQC and 3D $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC) were acquired. The TOCSY experiments were performed with spin-lock times of 80 ms. In addition, a 2D $^1\text{H}/^1\text{H}$ -TOCSY with a spin-lock time of 6 ms was acquired in order to obtain COSY-type information with less spectral overlap. A mixing time (τ_m) of 150 ms was used in the NOESY experiments. The water signal suppression in the homonuclear one- and two-dimensional ^1H experiments was achieved by selective presaturation during the relaxation delay, with the carrier placed in the center of the spectrum on the water resonance. All heteronuclear experiments made use of pulsed field gradients for coherence selection and artifact suppression, and utilized gradient sensitivity enhancement schemes wherever appropriate (Muhandiram and Kay, 1994). All NMR experiments were acquired in a phase-sensitive mode at 298 K. The States-TPPI or echo/antiecho method was used to obtain quadrature detection in the indirectly-detected dimension. The chemical shifts were referenced to external 2,2-dimethyl-2-silapentane-5-sulfonate in order to ensure consistency among all spectra (Wishart et al., 1995).

All NMR spectra were processed on a Silicon Graphics O2 workstation using the XWINNMR 3.5 software package (Bruker, Rheinstetten). A 90° phase-shifted squared sine-bell function was used for apodization in all dimensions. After Fourier transformation, polynomial base-line correction was applied to the processed spectra in the directly-detected dimension. Peak picking and data analysis of the transformed spectra were performed using the AURELIA 2.5.9 (Bruker, Rheinstetten) and FELIX 2000 (Accelrys Inc., San Diego, U.S.A.) software packages.

2.2.4.1.3. Resonance assignment

The sequence-specific ^1H and ^{15}N resonance assignments of FKBP38³⁵⁻¹⁵³ were determined according to the classical assignment strategy (Wüthrich, 1986), using the experiments from section 2.2.4.1.2.

2.2.4.1.4. Structure calculation and refinement

For the structure calculation, NOE-derived distance restraints were determined from 2D $^1\text{H}/^1\text{H}$ -NOESY and 3D $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC spectra. The NOE peaks were first automatically assigned on the basis of chemical shift values with the program *nmr2st* (Pristovšek et al., 2000). An internal calibration was used to set the upper distance limits, based on the intensities of characteristic intra- and inter-strand NOEs within the β -sheet structure as well as of sequential and medium-range NOEs within the α -helix. The integrated peak intensities were converted into approximate inter-proton distances by normalizing against the calibrated intensities. The upper distance limits were subsequently classified into different categories of 2.5, 3.5, 4.5 and 6.0 Å. A pseudo-atom correction was applied for magnetically equivalent protons (Wüthrich et al., 1983). No hydrogen bond constraints were used in the structure calculation.

The structures were calculated on a Silicon Graphics O2 workstation with the program DYANA 1.5 (Güntert et al., 1997), which uses a simulated annealing algorithm combined with torsion angle dynamics. Starting *ab initio*, 100 conformers were calculated in 8000 annealing steps each. For the structure refinement an iterative strategy was used; after each round of structure refinement, the newly computed NMR structures were employed to (i) assign ambiguous NOE cross-peaks, (ii) correct erroneous assignments, and (iii) loosen the NOE distance bounds if spectral overlap was deduced. In the last stages of the structure calculation, the stereospecific assignment of prochiral groups was carried out, also in an iterative manner, with the program GLOMSA (Güntert et al., 1991). At the end, nearly all prochiral amide (6), isopropyl (26) and methylene (76) groups were stereospecifically assigned.

In the last run of calculation the structures were computed using 1585 meaningful distance restraints, obtained out of a total of 2191 NOE assignments. The 20 best DYANA conformers were subsequently submitted to a restrained energy minimization (i.e. with NOE-derived distance restraints), carried out with the DISCOVER module of the INSIGHT 2000 software package (Accelrys, San Diego, U.S.A.). For the restrained energy minimization, the consistent valence force field (Dauber-Osguthorpe et al., 1988) was used, with a dielectric constant equal to r (distance in Å). A force constant of $20 \text{ kcal } \text{Å}^{-2} \text{ mol}^{-1}$ was applied in the NOE restraint terms. The 20 final selected FKBP38³⁵⁻¹⁵³ conformers were analyzed with PROCHECK-NMR (Laskowski et al., 1996).

2.2.4.2. Study of the interactions of FKBP38³⁵⁻¹⁵³ with Ca²⁺ and Mg²⁺

For the study of the interactions of FKBP38³⁵⁻¹⁵³ with Ca²⁺, a sample consisting of 0.4 mM ¹⁵N-enriched FKBP38³⁵⁻¹⁵³, dissolved in 10 mM MES (pH 6.8) and 100 mM KCl, was titrated with a 1 M CaCl₂ solution, to obtain Ca²⁺ concentrations of 0, 0.14, 3.7 and 7.3 mM. At each of the titration points, a ¹H/¹⁵N-HSQC spectrum was collected, processed and analyzed as described in section 2.2.4.1.2.

A 0.8 mM solution of non-labelled FKBP38³⁵⁻¹⁵³ was also titrated with 1 M CaCl₂, under the same conditions as in the previously described experiment. In this case, Ca²⁺ concentrations of 0, 1, 2, 3, 6, 9 and 12 mM were obtained. During this titration, one-dimensional ¹H spectra were collected and processed using standard procedures.

To study the interaction of FKBP38³⁵⁻¹⁵³ with Mg²⁺, a 0.1 mM solution of non-labelled FKBP38³⁵⁻¹⁵³, dissolved in 10 mM MES (pH 6.8) and 100 mM KCl, was titrated with 1 M MgCl₂, to obtain Mg²⁺ concentrations of 0, 10 and 20 mM. In the course of this titration, one-dimensional ¹H spectra were collected and processed using standard procedures.

As a control experiment, a 0.2 mM solution of ¹⁵N-labelled FKBP12 was titrated with 1 M CaCl₂ to a Ca²⁺ concentration of 7.3 mM. ¹H/¹⁵N-HSQC spectra of FKBP12 were collected before and after the addition of CaCl₂. Data acquisition, processing and analysis were carried out as described in section 2.2.4.1.2.

2.2.4.3. Study of the interactions between FKBP38 and CaM

2.2.4.3.1. Resonance assignments of apo-CaM, holo-CaM and FKBP38²⁹⁰⁻³¹³

All NMR data were acquired and processed as described in section 2.2.4.2.2., using a DRX500 spectrometer (Bruker, Rheinstetten) that operated at 500.13 MHz proton resonance frequency and was equipped with a 5 mm inverse triple-resonance (¹H/¹³C/¹⁵N) probe with XYZ-gradient coils.

No previous assignments of apo- and holo-CaM under the experimental conditions used in this study have been reported. Moreover, the construct of CaM used in this study contained an N-terminal His-tag. Therefore, the amide resonances of apo- and holo-CaM had to be newly assigned.

For apo-CaM, a complete resonance assignment of CaM from *Xenopus laevis* (100% identical to human CaM) at 23 °C and pH 6.3 was kindly provided by Dr. Ad Bax (NIH, Bethesda, USA) and served as starting point. The assignment of the holo-CaM amide resonances was carried out starting from a previous assignment of holo-CaM from *Drosophila melanogaster* (presenting three amino acids substitutions, i.e. Y99F, D129N and Q143T, with respect to human CaM), which had been performed at 47 °C and pH 6.3 (Ikura et al. 1990). However, in order to account for chemical shift differences due to (i) the experimental conditions and (ii) alterations in the amino acid sequence, a full set of 2D $^1\text{H}/^{15}\text{N}$ -HSQC, 3D $^1\text{H}/^{15}\text{N}$ -TOCSY-HSQC and 3D $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC spectra was collected for both apo- and holo-CaM to obtain sequence-specific resonance assignments at the chosen conditions.

The resonance assignment of FKBP38²⁹⁰⁻³¹³ was performed with a partially ^{15}N -labelled sample, where the residues Leu292, Ala297, Ala305 and Leu311 as well as the N^ϵ of Gln299 were ^{15}N -labelled. For this assignment, 2D ^{15}N -decoupled $^1\text{H}/^1\text{H}$ -TOCSY and $^1\text{H}/^1\text{H}$ -NOESY as well as 2D $^1\text{H}/^{15}\text{N}$ -HSQC, 3D $^1\text{H}/^{15}\text{N}$ -TOCSY-HSQC and 3D $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC spectra were collected and assigned.

2.2.4.3.2. Chemical shift perturbation experiments

The chemical shift perturbation experiments (CSP) were carried out at two different conditions in order to determine the interactions of FKBP38³⁵⁻¹⁵³ with (i) apo- and (ii) holo-CaM. The interactions with apo-CaM were measured in 20 mM sodium phosphate buffer (pH 6.8, 0.05% (w/v) NaN_3 and 5% (v/v) D_2O), whereas the interactions with holo-CaM were measured in 10 mM MES buffer (pH 6.8, 100 mM KCl, 6 mM CaCl_2 , 0.05% (w/v) NaN_3 and 5% (v/v) D_2O). In all experiments the protein concentrations were in the range 0.5-0.7 mM ^{15}N -labelled protein and 1.5-2.1 mM non-labelled protein, in order to obtain a 1:3 molar ratio. To ensure identical conditions in each CSP experiment, the samples were prepared according to the following procedure:

- 1) Two 0.5 ml solutions, each containing the required amount of FKBP38³⁵⁻¹⁵³ and CaM (one protein ^{15}N -labelled and the other non-labelled), were dialyzed twice against 3 l buffer (containing all the above-mentioned components except D_2O).
- 2) The required amount of D_2O was added to the solution of the ^{15}N -labelled protein and a $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of the resulting sample, representing the “free” protein, collected.
- 3) The second (non-labelled) protein was added, the mixture of both proteins washed in a concentrator once with buffer, and then reduced to a final volume of 0.5 ml.

4) The required amount of D₂O was added again, the pH value checked (and corrected if necessary), and a ¹H/¹⁵N-HSQC spectrum of the resulting “complexed” protein was acquired.

Finally, the two ¹H/¹⁵N-HSQC spectra were compared, and the resulting alterations in the ¹H and ¹⁵N chemical shift values used to calculate the combined chemical shift perturbation for each residue according to the following equation (Mulder et al., 1999):

$$\Delta\delta = [(\Delta\delta_{1H})^2 + (\Delta\delta_{15N} / 6.5)^2]^{1/2}$$

As control experiments, 0.2 mM solutions of ¹⁵N-labelled FKBP12 were titrated with 3-fold excess of either apo- or holo-CaM by following the same procedure.

2.2.4.3.3. Docking calculations

The three-dimensional structures of the FKBP38³⁵⁻¹⁵³/apo-CaM, FKBP38³⁵⁻¹⁵³/holo-CaM and FKBP38²⁹⁰⁻³¹³/holo-CaM complexes were determined with the program HADDOCK (High Ambiguity Driven protein-protein DOCKing) (Dominguez et al., 2003), which is implemented in the CNS program suite (Brunger et al., 1998) and uses python scripts derived from ARIA (Linge et al., 2001) for automation. HADDOCK makes use of biophysical interaction data, such as chemical shift perturbations provided by NMR titration experiments, which are introduced into the structure calculation as ambiguous interaction restraints (AIRs) to drive the docking process. In the present work, the following independent sets of amide chemical shift perturbations were available:

For the FKBP38³⁵⁻¹⁵³/apo-CaM complex:

- ¹⁵N-labelled FKBP38³⁵⁻¹⁵³ titrated with non-labelled apo-CaM
- ¹⁵N-labelled apo-CaM titrated with non-labelled FKBP38³⁵⁻¹⁵³

For the FKBP38³⁵⁻¹⁵³/holo-CaM complex:

- ¹⁵N-labelled holo-CaM titrated with non-labelled FKBP38³⁵⁻¹⁵³
- The titration of ¹⁵N-labelled FKBP38³⁵⁻¹⁵³ with non-labelled holo-CaM led to a fairly rapid denaturation of FKBP38³⁵⁻¹⁵³ and consequently no observable chemical shift changes. Hence, no CSP data could be obtained. In this case, the CSP data from the equivalent experiment with apo-CaM were used for the HADDOCK calculations.

For the FKBP38²⁹⁰⁻³¹³/holo-CaM complex:

- Partially ^{15}N -labelled FKBP38²⁹⁰⁻³¹³ (where the residues Leu292, Ala297, Ala305 and Leu311 as well as the N^ε of Gln299 are ^{15}N -labelled) titrated with the non-labelled C-terminal domain of holo-CaM.
- Partially ^{15}N -labelled FKBP38²⁹⁰⁻³¹³ titrated with non-labelled holo-CaM.
- ^{15}N -labelled holo-CaM titrated with non-labelled FKBP38²⁹⁰⁻³¹³.

From each independent data set, the residues with (i) the most pronounced chemical shift perturbations or (ii) relaxation properties displaying a considerable change upon binding (i.e. changes in signal line-widths that subsequently lead to either appearance or disappearance of peaks upon binding) were selected as “active AIRs” for the HADDOCK calculations, as long as their relative surface accessibilities were higher than 20%. In the case of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, the cut-off for the surface accessibility was not applied, as the FKBP38 segment was found to bind to the inner cavity of the C-terminal holo-CaM domain.

The following atomic coordinates were used to (i) calculate the surface accessibilities with the program NACCESS (Hubbard and Thornton, 1993) and (ii) perform the subsequent docking calculations:

For the FKBP38³⁵⁻¹⁵³/apo-CaM complex:

- NMR structure of FKBP38³⁵⁻¹⁵³ (PDB ID code 2F2D, 20 conformers)
- NMR structure of apo-CaM (Kuboniwa et al. 1995; PDB ID code 1CFD, minimized average structure)

For the FKBP38³⁵⁻¹⁵³/holo-CaM complex:

- NMR structure of FKBP38³⁵⁻¹⁵³ (PDB ID code 2F2D, 20 conformers)
- Crystal structure of holo-CaM (Babu et al., 1988; PDB ID code 3CLN)

For the FKBP38²⁹⁰⁻³¹³/holo-CaM complex:

- FKBP38²⁹⁰⁻³¹³ segment of the simulated FKBP38³⁵⁻³¹³ structure (see section 2.2.5.)
- Crystal structure of holo-CaM (Babu et al., 1988; PDB ID code 3CLN)

For the docking calculations of the FKBP38³⁵⁻¹⁵³/apo-CaM and FKBP38³⁵⁻¹⁵³/holo-CaM complexes, 400 structures each were first calculated using the rigid body docking protocol of HADDOCK. Next, the 20 structures showing the lowest AIR violations were submitted to a semi-flexible simulated annealing in torsion angle space, where the side-chains of the residues forming the protein-protein interface were left flexible. The resulting structures were finally refined in an 8 Å shell of explicit TIP3P (Jorgensen et al., 1983) water molecules. The same

procedure was used for the calculation of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, but only 100 structures were calculated in the first stage of the calculation, and the 20 best structures further refined.

2.2.5. Molecular dynamics simulations

The initial structures for the MD simulations of FKBP38³⁵⁻³¹³, holo-CaM and the FKBP38³⁵⁻³¹³/CaM complexes were created from structures available at the RCSB database by using the INSIGHT II module of the INSIGHT 2000 software package (Accelrys, San Diego, U.S.A.).

The initial structure for the simulation of FKBP38³⁵⁻³¹³ was created by combining the NMR structure of its FKBP domain obtained in this work (PDB ID code 2F2D, conformer 1) and the backbone structure of FKBP51 (Sinars et al., 2003; PDB ID code 1KT1). The segment Pro382-Lys386, which is missing in the FKBP51 structure, was taken from the structure of FKBP52 (Wu et al., 2004; PDB ID code 1P5Q). After superposing the backbone atoms of FKBP38³⁵⁻¹⁵³ and the second FKBP domain of FKBP51, several ϕ and ψ angles in the loop connecting the FKBP and TPR domains of FKBP51 were modified in order to account for differences in the length of this loop between the two proteins. The same procedure was applied in other loops of the TPR domain wherever required. Afterwards, amino acid substitutions were applied to adjust the TPR domain to the FKBP38 sequence. The thus obtained structure combines the TPR domain backbone structure of FKBP51, as well as its relative FKBP-TPR domain orientation, with the structure of FKBP38³⁵⁻¹⁵³.

The starting structures for the simulation of holo-CaM with a flexible linker were created from the crystal structure of holo-CaM (Babu et al., 1988; PDB ID code 3CLN). Two starting structures with extended linkers were produced, one with a linker from Glu78 to Ser81 and another with a linker from Met76 to Ser81. To achieve this, the ψ angles of the residues forming the linker were modified to values in the β -sheet region, thus producing extended backbone conformations.

For the simulation of the FKBP38³⁵⁻³¹³/holo-CaM complex, the starting structure was created from the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, which had been obtained by docking calculations with HADDOCK as described in section 2.2.4.3.3., as well as from one MD structure each of FKBP38³⁵⁻³¹³ and holo-CaM. First, the MD structures of holo-CaM and FKBP38³⁵⁻³¹³ were superposed to the C-terminal domain of holo-CaM and FKBP38²⁹⁰⁻³¹³ in the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, respectively. Afterwards, the C-terminal domain of the holo-CaM MD structure

and the segment FKBP38²⁹⁰⁻³¹³ of the FKBP38³⁵⁻³¹³ structure were deleted.

In an analogous manner, the starting structure for the simulation of the FKBP38³⁵⁻³¹³/holo-CaM complex was combined with the NMR solution structure of apo-CaM (Kuboniwa et al., 1995; PDB ID code 1CFD, minimized average structure) to obtain a starting structure for the simulation of the FKBP38³⁵⁻³¹³/semiloading-CaM complex, where the N-terminal domain of CaM is free of Ca²⁺. This structure was obtained by replacing the N-terminal CaM domain in the FKBP38³⁵⁻³¹³/holo-CaM complex with the N-terminal domain of the apo-CaM structure.

The MD simulations were performed using the GROMACS 3.3 program package (van der Spoel et al., 2005; www.gromacs.org) and the gromos96 (43a1) force field (van Gunsteren et al., 1996) provided by GROMACS. In all simulations, the simulated system consisted of either a single protein molecule or a protein/protein complex, 100 mM NaCl and SPC water molecules (Berendsen et al., 1981) in a cubic box. The box dimensions were set more than 3 Å longer than the protein or protein/protein complex diameter. Prior to the MD simulations, the starting geometries were optimized by molecular mechanics (MM) using the steepest descent algorithm (1000 steps) to remove tight contacts at the protein-solvent and ion-solvent interfaces.

The MD simulations were performed at constant temperature (coupling the system to a Berendsen thermostat set to 300 K, bath relaxation time 0.1 ps) and pressure (isotropic coupling to 1 bar at a relaxation time of 1 ps) (Berendsen et al., 1984) with periodic boundary conditions. The leapfrog algorithm was used for time propagation with a time step of 0.002 ps. For the calculation of the van der Waals interactions, a twin range cut-off radius of 1 Å was used. The neighbor list was updated every 20 steps within a cut-off radius of 1 Å. The Fast Particle-Mesh Ewald method (Darden et al., 1993; Essmann et al., 1995) was applied to calculate the electrostatic interactions, with a maximum grid spacing of 0.12 nm for the fast Fourier transformation grid and 4th order interpolation. All bond lengths were constrained with the LINCS algorithm (Hess et al., 1997). In all simulations involving Ca²⁺-bound forms of CaM, additional distance restraints of 2.59 Å were imposed between the Ca²⁺ ions and the protein atoms coordinating Ca²⁺, analogous to the NMR structure determination of CaM/target peptide complexes (Elshor et al., 1999). The protein geometries were recorded every 500 time steps (1 ps). All simulations were performed on an Intel Pentium 4 3.20 GHz processor, with effective calculation times ranging from 4 to 7 days per nanosecond.

At the beginning of the MD simulations, atomic velocities were generated at 290 K with a Maxwellian distribution. Next, three short consecutive position-restrained MD runs were

performed for equilibration, each consisting of 10,000 time steps of 0.0005, 0.001 and 0.002 ps, respectively. Finally, unrestrained MD simulations were performed for 5 ns in the case of holo-CaM and 9 ns in the case of FKBP38³⁵⁻³¹³.

For the simulation of the FKBP38³⁵⁻³¹³/holo-CaM and FKBP38³⁵⁻³¹³/semiloaded-CaM complexes, three consecutive restrained MD runs were performed after the equilibration runs, with incorporation of small sets of distance restraints obtained from the HADDOCK structures of the FKBP38³⁵⁻¹⁵³/holo-CaM complex (for the FKBP38³⁵⁻³¹³/holo-CaM complex simulation), the FKBP38³⁵⁻¹⁵³/apo-CaM complex (for the FKBP38³⁵⁻³¹³/semiloaded-CaM complex simulation), and the FKBP38²⁹⁰⁻³¹³/holo-CaM complex (for both simulations). In these restrained MD simulations, the restraints were used in a fashion typical for NMR-based structure calculations (i.e. in form of (i) quadratic potentials below a specified lower bound and between two specified upper bounds and (ii) linear potentials beyond the largest bound). The force constant for the distance restraints was progressively increased in the three runs, from 200 to 500 to 1000 kJ mol⁻¹ nm⁻², in order to produce a smooth trajectory towards the final structure. The simulation time for these MD runs was 0.5 ns each (i.e. 1.5 ns in total).

2.2.6. Crystal structure analysis of FKBP38³⁵⁻¹⁵³

The crystallization of FKBP38³⁵⁻¹⁵³ was performed using the sitting-drop vapor diffusion method. First, the protein was screened with the crystallization kits JBScreen Classic 1-4 and Crystal ScreenTM 1-2 (96 crystallization conditions each), employing protein concentrations of 5, 10 and 20 mg/ml. Small crystals were found in both plates at the same condition, where the protein (at a concentration of 20 mg/ml) was crystallized with a reservoir solution consisting of 30% PEG4000, 0.2 M MgCl₂ and 0.1 M TRIS (pH 8.5). In order to improve the quality of the crystals, a screening around this condition was carried out, with PEG4000 concentrations of 10, 20 and 30%, as well as pH values of 7.5, 8.0, 8.5 and 9.0. Furthermore, a second set of conditions was tested, where MgCl₂ was substituted by CaCl₂. The crystals displaying the best diffraction results (Figure 11) were finally obtained with a reservoir solution consisting of 30% PEG4000, 0.2 M CaCl₂ and 0.1 M TRIS (pH 7.5).

X-ray diffraction measurements were performed at the PSF beamline of the BESSY synchrotron facility (Berlin), where the crystals were cooled to 100 K. The beamline was tuned to a wavelength of 0.95373 Å and a MAR-225 MOSAIC CCD detector was used at a crystal-to-detector distance of 100 mm. The data were collected in a range of 0° to 180°, applying 1° steps

that amounted to a total of 180 images (3 sec collection time each).

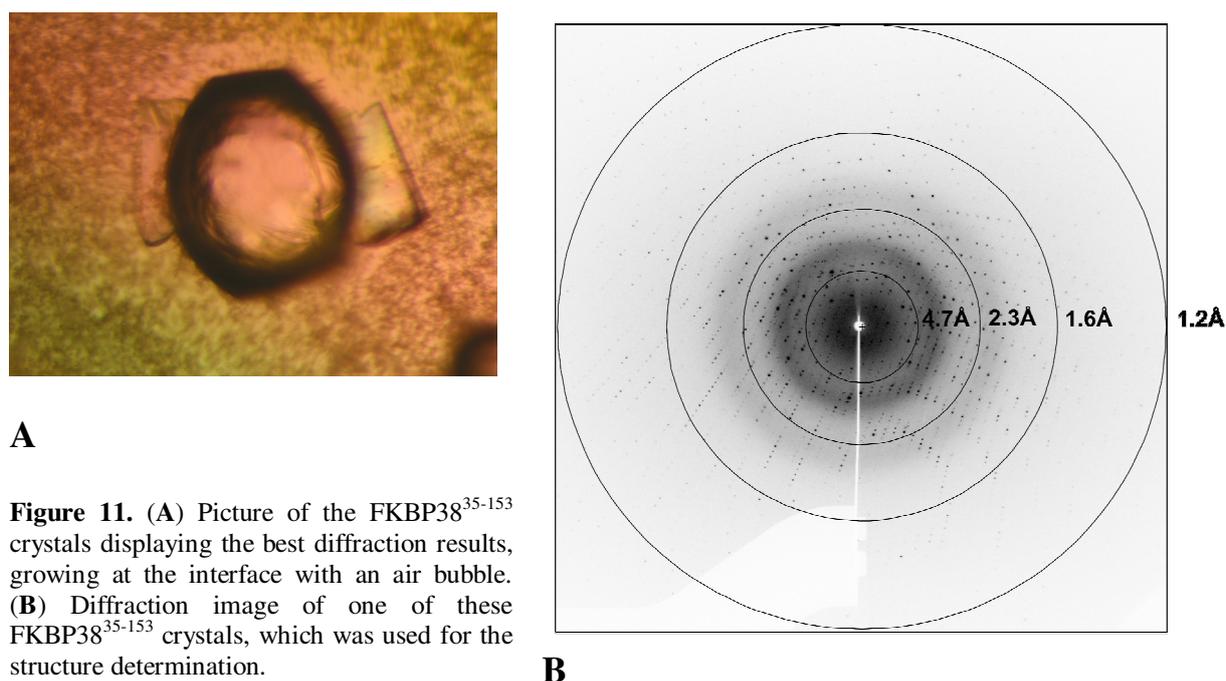

Figure 11. (A) Picture of the FKBP38³⁵⁻¹⁵³ crystals displaying the best diffraction results, growing at the interface with an air bubble. (B) Diffraction image of one of these FKBP38³⁵⁻¹⁵³ crystals, which was used for the structure determination.

Data processing was carried out with the programs MOSFLM (Leslie, 1994) and SCALA, which is part of the CCP4 software package (Collaborative computational project, 1994). The FKBP38³⁵⁻¹⁵³ structure was determined by molecular replacement using the program PHASER and a previously determined X-ray structure of FKBP38³¹⁻¹⁴⁸ as search model. Structure refinement was performed with the program REFMAC5 of the CCP4 package. Statistics about the data collection and refinement are presented in Table 2.

Table 2. X-ray data collection and refinement statistics.

Data collection		Refinement	
Space group	P2 ₁	Resolution (Å)	60.3-1.1
Cell dimensions		No. reflections (work/test)	18,643/2,118
<i>a</i> , <i>b</i> , <i>c</i> (Å)	29.06, 60.29, 30.84	<i>R</i> _{work} / <i>R</i> _{free}	13.3/15.3
α , β , γ (°)	90, 97.59, 90	No. atoms	
Resolution (Å)	1.05	Protein	900
<i>R</i> _{merge}	4.3 (11.8)	Water	279
<i>I</i> / σ <i>I</i>	20.1 (5.6)	<i>B</i> -factors	
Completeness (%)	90.4 (52.4)	Protein	8.65
Redundancy	3.3 (2.1)	Water	22.88
		R.m.s deviations:	
		Bond lengths (Å)	0.011
		Bond angles (°)	1.55

The values in parentheses are for the highest-resolution shell (1.05-1.11 Å).

3. Results and discussion

3.1. NMR assignment of the ^1H and ^{15}N resonances of FKBP38³⁵⁻¹⁵³

The sequential assignment of the ^1H and ^{15}N resonances of FKBP38³⁵⁻¹⁵³ (Figure 12) was carried out using the classical assignment strategy (Wüthrich, 1986), whereby the spins systems corresponding to the different amino acids are first identified by means of scalar connectivities (from TOCSY and COSY experiments) and then sequentially assigned via NOE connectivities (from NOESY experiments, Figure 13). Spectral overlap arising from amide protons resonances with similar chemical shifts is overcome by the measurement of heteronuclear experiments on ^{15}N -labelled protein, which allow the introduction of an additional ^{15}N dimension displaying higher spectral dispersion. Thus, three-dimensional ^{15}N -edited TOCSY and NOESY experiments ($^1\text{H}/^{15}\text{N}$ -TOCSY-HSQC and $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC) were used for the sequential assignment (Figure 13B). Nearly all backbone and side-chain ^{15}N and ^1H resonances, with the exception of the backbone amide groups of the two cloning artifacts Met33 and Arg34, were assigned (Table 3). The assignment has been deposited at the BioMagResBank data base under accession number BMRB-6902.

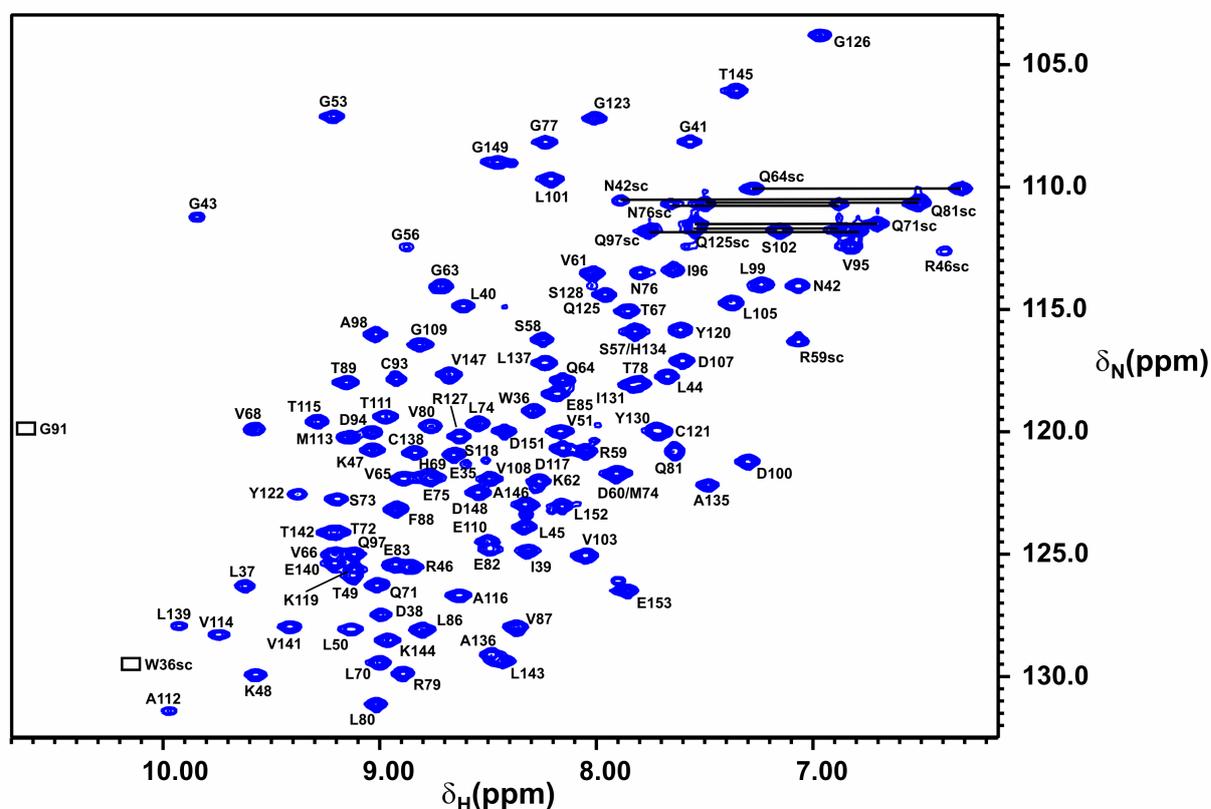

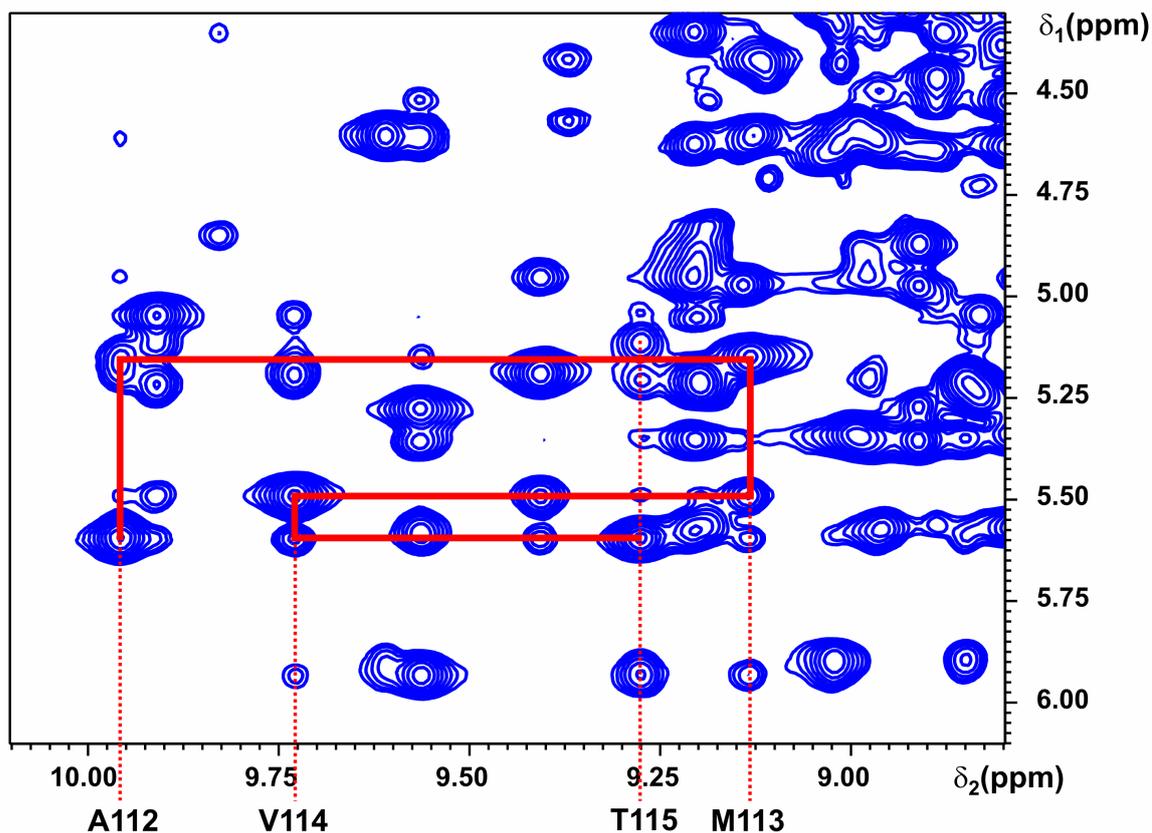

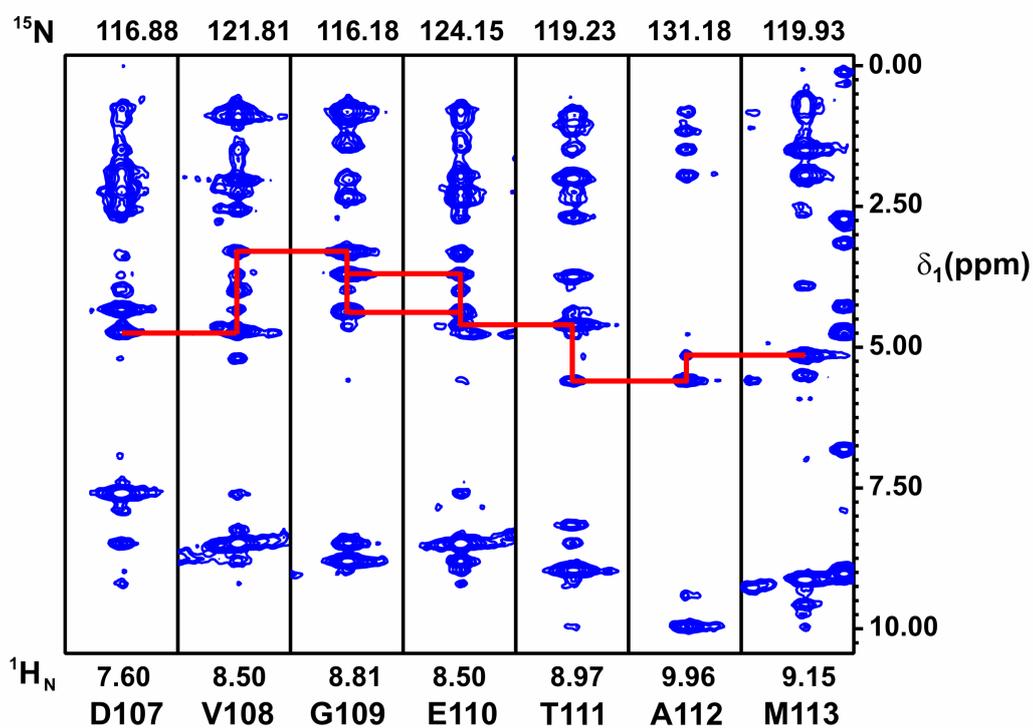

Figure 12. Two-dimensional $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of FKBP38³⁵⁻¹⁵³ recorded at 500.13 MHz. The sequence-specific assignment of the amide resonances is indicated. Boxes indicate signals that appear below the plot level. Side-chain resonances are marked with the suffix sc. Arginine side-chain signals are folded in the nitrogen dimension. Horizontal lines connect signals that belong to NH_2 groups.

A

B

Figure 13. (A) Section of the NOESY spectrum (recorded at 700.13 MHz) of FKBP38³⁵⁻¹⁵³, showing part of the fingerprint region. The H_N - H_α resonances corresponding to the segment Ala112-Thr115 are sequentially assigned via $\text{H}^\text{N}(i)$ - $\text{H}^\alpha(i-1)$ NOE connectivities. (B) Selection of ^{15}N slices from the 3D $^1\text{H}/^{15}\text{N}$ -NOESY-HSQC of FKBP38³⁵⁻¹⁵³ recorded at 500.13 MHz. The H_N - H_α resonances corresponding to the segment Asp107-Met113 are assigned sequentially via $\text{H}^\text{N}(i)$ - $\text{H}^\alpha(i-1)$ NOE-connectivities.

Table 3. ^1H and ^{15}N resonance assignments (in ppm) of FKBP38³⁵⁻¹⁵³ at 298 K and pH 6.7. Stereospecific assignments are indicated by IUPAC numbering.

3.2. Three-dimensional structure of FKBP38³⁵⁻¹⁵³

The solution structure of FKBP38³⁵⁻¹⁵³ was determined from a set of 1585 distance restraints, derived from a total of 2191 NOE assignments. The atomic coordinates were deposited at the RCSB database under PDB ID code 2F2D. A superposition of the final 20 energy-minimized conformers is shown in Figure 14A. The NOE connectivity pattern between the backbone protons was used to determine the secondary structure elements of the protein. A large number of strong sequential $d_{\alpha N}(i, i+1)$ NOE connectivities indicated predominantly β -strand elements. Additional inter-strand NOEs revealed an antiparallel β -sheet structure consisting of 6 β -strands: Leu37-Asp38 (β A), Leu45-Thr49 (β B), Gln64-Leu74 (β C), Thr78-Leu90 (β D), Glu110-Asp117 (β E) and Ala136-Asp148 (β F). The fourth β -strand β D, however, is interrupted by two bulges at residues Val80 and Pro84; in addition, β -strand β F shows a bulge at residue Lys144. Furthermore, based on a series of strong sequential $d_{NN}(i, i+1)$, weaker $d_{\alpha N}(i, i+1)$, as well as a dense network of medium-range $d_{NN}(i, i+2)$, $d_{\alpha N}(i, i+2)$, $d_{\alpha N}(i, i+3)$, $d_{\alpha\beta}(i, i+3)$ and $d_{\alpha N}(i, i+4)$ connectivities, an α -helix element spanning residues Gln97-Pro104 has been identified between β -strands β D and β E, with a slight kink at residue Val103. A helical loop was found in the segment Ser118-Tyr122. The presence of a strong sequential $d_{\alpha\alpha}(i, i+1)$ NOE connectivity between Ser128 and Pro129 (located in the extended loop β D- β E) revealed that this peptide bond is in *cis* conformation; all other proline residues are *trans* forms, as indicated by the observation of strong NOE connectivities between the proline C_{δ} protons and the respective H_{α} of the preceding residue (Wüthrich, 1986).

Figure 14. Representation of the FKBP38³⁵⁻¹⁵³ structure. **(A)** Stereo view showing the C^α traces of the 20 selected FKBP38³⁵⁻¹⁵³ conformers. **(B)** Ribbon diagram displaying the secondary structure elements of a single FKBP38³⁵⁻¹⁵³ conformer. The helical segments are colored in red, while β-strands are represented as blue arrows.

Table 4. Structural statistics of the final 20 energy-minimized FKBP38³⁵⁻¹⁵³ conformers.

NOE-derived distance restraints:	1585
Intraresidual ($i = j$)	288
Sequential ($ i - j = 1$)	521

Heavy atom RMSD (secondary structure elements)	1.77 ± 0.25

^a N, C^α, C' and O.

The overall structure of the 20 energy-minimized FKBP38³⁵⁻¹⁵³ conformers shows a backbone RMSD for the non-terminal residues (Trp36-Gly149) of $1.73 \pm 0.22 \text{ \AA}$ and only few violations of the experimental constraints (Table 4). A six-stranded antiparallel β-sheet with a +1, +3, +1, -3, +1 topology curves around the central helix, thus forming a so-called “half β-barrel”. Excluding the long Ser118-Ala135 loop, which covers the proposed FK506-binding pocket and shows a fairly high conformational variability, the RMSD of the backbone structure drops down to $1.48 \pm 0.18 \text{ \AA}$; excluding all loops structures, the backbone RMSD of only the secondary structure

elements (one α -helix and six β -strands) decreases further to 1.08 ± 0.13 Å. The analysis of the backbone dihedral angles ϕ and ψ , displayed in the Ramachandran diagram (Figure 15), shows that 98% of all non-glycine/non-proline residues in FKBP38³⁵⁻¹⁵³ fall within the allowed regions of the conformational space.

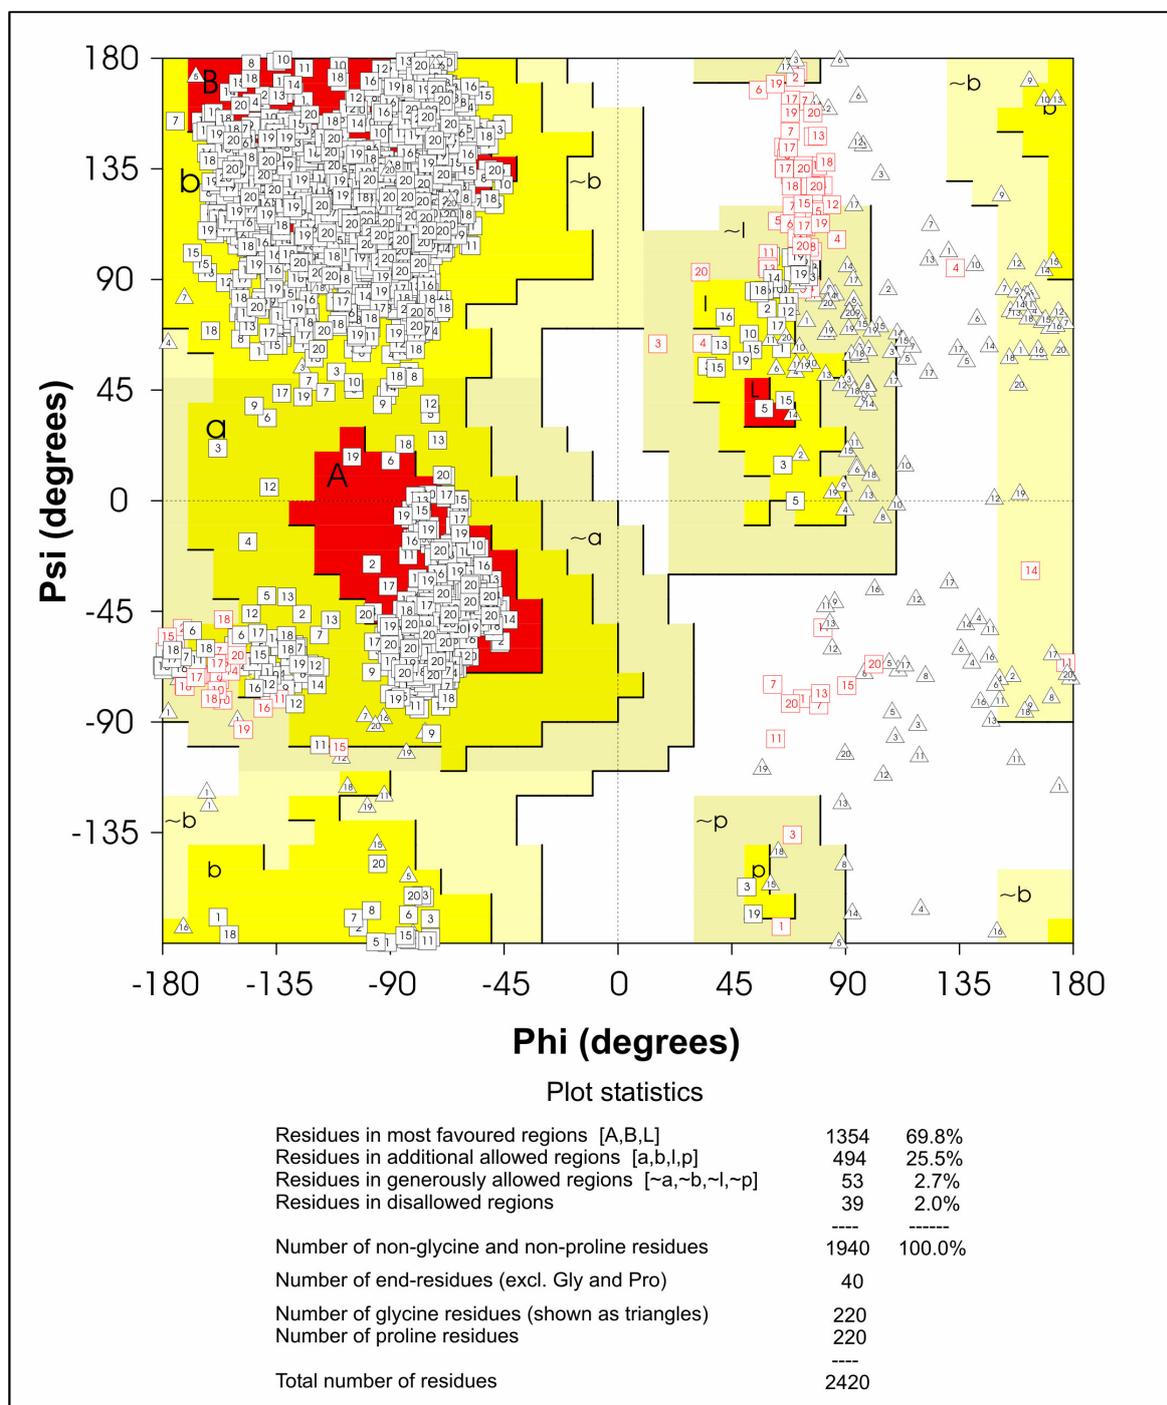

Figure 15. Ramachandran diagram of the final 20 energy-minimized FKBP38³⁵⁻¹⁵³ conformers.

The overall structure of FKBP38³⁵⁻¹⁵³ (Figure 14B) resembles the typical fold of FKBP domains, although this particular domain exhibits no PPIase activity and is not able to bind the low-molecular-weight inhibitor FK506 in the absence of CaM. A comparison with the crystal

structure of the immunosuppressive FKBP12/FK506 complex (PDB ID code 1FKJ) (Figure 16A) shows no major structural differences, as reflected by an average backbone RMSD of 1.70 ± 0.19 Å between the structure of FKBP12 and the 20 FKBP38³⁵⁻¹⁵³ conformers (more precisely: segments Leu45-Gly53, Gly56-Gly77, Val95-Thr115 and Ala136-Leu143), which is comparable to the value obtained for the NMR ensemble itself (Table 4). The main structural difference between both structures is observed in β -strand β D of FKBP38³⁵⁻¹⁵³ (β 5 of FKBP12) within the segment Glu83-Leu86 (Ser39-Phe46 in FKBP12) (Figure 16A). In the case of FKBP38³⁵⁻¹⁵³, β -strand β D is interrupted by only a small bulge affecting the positions of residues Pro84 and Glu85, whereas FKBP12 exhibits a larger loop (Arg40 – Pro45) with 4 additional residues. As a consequence, the side-chain of Glu83 in FKBP38³⁵⁻¹⁵³ takes on a different orientation than the corresponding Ser39 side-chain in FKBP12, thereby extending into the putative FK506-binding site of FKBP38³⁵⁻¹⁵³ in a similar orientation as Arg42 in FKBP12, but getting much closer to the FK506 molecule than the Arg42 side-chain (Figure 16B). In addition, the long β E- β F loop, which shows a high degree of conformational variability in the 20 conformers of the FKBP38³⁵⁻¹⁵³ solution structure, is slightly closer to the binding site than in FKBP12. Residue His87 of FKBP12, located in this loop, is replaced by the larger side-chain of Arg127 in FKBP38³⁵⁻¹⁵³, which also shows a high degree of conformational variability and reaches into the putative binding pocket in 80% of the conformers, possibly blocking the access to the binding site (Figure 16C). Moreover, Arg127 apparently can form salt bridge contacts inside the binding pocket with both Glu83 and Asp94 (either separately or simultaneously), as observed in several of the NMR conformers (Figure 16D); these salt bridge interactions (centroid distances between the guanidinium and carboxylate groups < 4 Å) might stabilize a “closed conformation” of the FKBP38³⁵⁻¹⁵³ entry portal region in contrast to FKBP12. Nevertheless, an R127A mutant of FKBP38³⁵⁻¹⁵³ showed no constitutive FKBP activity (Moutty, 2006), indicating that such salt bridge interactions cannot be the only reason for the inactivity of this FKBP domain. Hence, the lack of FKBP activity of FKBP38³⁵⁻¹⁵³ may be better explained by a combination of factors: (i) an active site closed by the β E- β F loop and (ii) the orientation of the Glu83 and Arg127 side-chains towards the putative FK506-binding site. Moreover, some amino acid replacements around the putative active site (i.e., FKBP38 segments Val80-Phe88, Gly91-Ile96 and Tyr120-Ile131) indicate a clear change in the net surface charge from +2 (or +3 if His87 is in the protonated state) in FKBP12 to -4 in FKBP38 (Figure 17). This charge difference of 6 (or 7) units in the surface potentials around the entry portal of the two related FKBP domains may be important for substrate discrimination, especially in the case of charged polypeptide substrates, and could therefore be an explanation for their distinct functional behaviors.

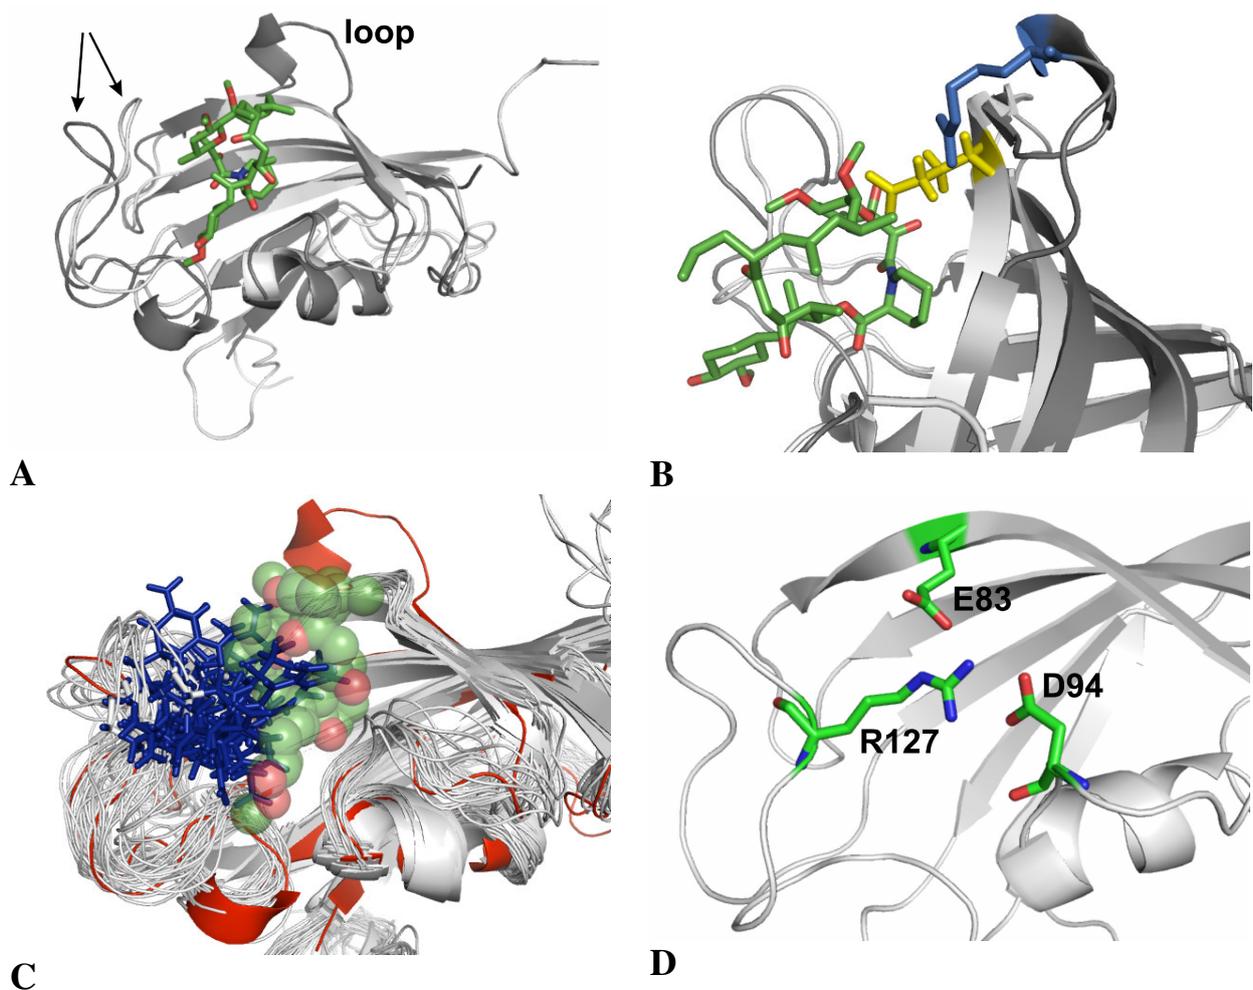

Figure 16. Structural features of FKBP38³⁵⁻¹⁵³. (A) Superposition of FKBP38³⁵⁻¹⁵³ (one conformer, represented as light gray ribbon) and the FKBP12/FK506 complex (dark gray ribbon with ligand as stick model colored by atom type; PDB ID code 1FKJ). The FKBP38³⁵⁻¹⁵³ βE-βF loop and the corresponding FKBP12 β2-β3 loop, which differ in their positions relative to the active site, are indicated by arrows. The additional loop Arg40-Pro45 in FKBP12 is labelled. (B) Close-up of (A) with the side-chains of Glu83 (FKBP38³⁵⁻¹⁵³) and Arg42 (FKBP12) displayed as yellow and blue sticks, respectively. (C) Superposition of the 20 selected FKBP38³⁵⁻¹⁵³ conformers (represented as gray ribbon) with the FKBP12/FK506 complex (red ribbon with ligand as transparent spheres colored by atom type). The Arg127 side-chains of the FKBP38³⁵⁻¹⁵³ conformers, which partially overlap with the FK506 ligand, are represented as blue sticks. (D) Close up of the FKBP38³⁵⁻¹⁵³ structure. The side-chains the residues Arg127, Glu83 and Asp94, forming two salt bridges in this conformer, are shown as stick models.

It had been reported that FKBP38 supposedly acts as an intrinsic inhibitor of the Ser/Thr protein phosphatase CaN (Shirane and Nakayama, 2003). This would implicate that the FKBP domain of FKBP38 can mimic the FKBP12/FK506 complex, which is an inhibitor of CaN. On the other hand, more recent reports indicate that FKBP38 cannot inhibit CaN in absence of bound FK506 (Kang et al., 2005; Weiwad et al., 2005). The interaction of the FKBP12/FK506 complex with CaN is mediated by the FK506 molecule and several FKBP12 residues surrounding this ligand (Figure 18), in particular the segments Lys34-Phe46 (corresponding to the β5 strand) and His87-Ile90 (part of the β2-β3 loop), which interact with CaN at the contact region between its two subunits (Griffith et al., 1995; Kissinger et al., 1995). The rather small structural differences between FKBP38³⁵⁻¹⁵³ and FKBP12 as well as the fact that no side-chains of FKBP38³⁵⁻¹⁵³, with

the exception of Arg127, would overlap with the outer part of the bound FK506 ligand, are a clear indication that FKBP38³⁵⁻¹⁵³ by itself cannot mimic the immunosuppressive FKBP12/FK506 complex. Hence, the structure of FKBP38³⁵⁻¹⁵³ supports the observation that FKBP38 in fact cannot bind CaN in the absence of bound FK506.

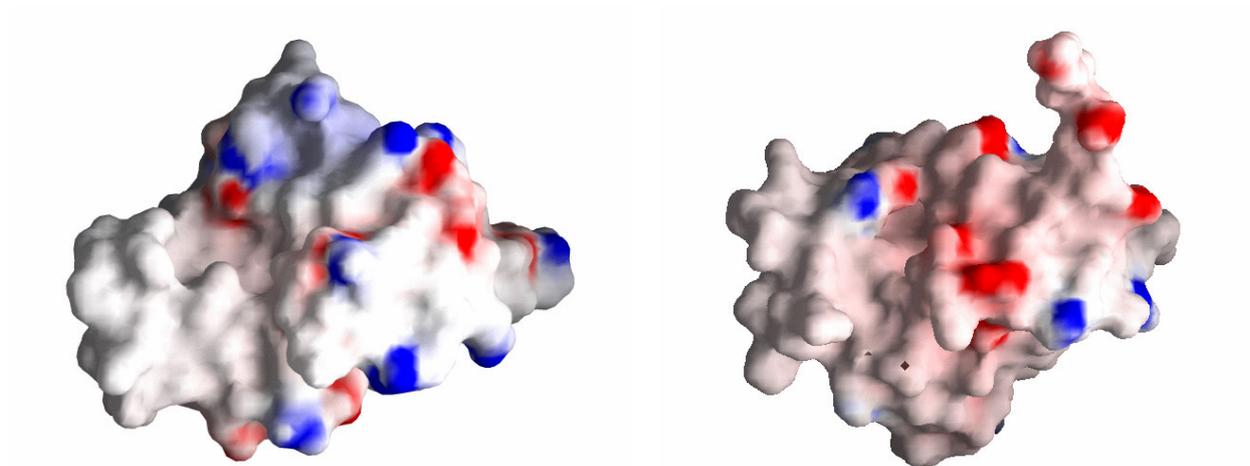

Figure 17. Surface potentials of FKBP12 (**left**) and FKBP38³⁵⁻¹⁵³ (**right**). Both proteins are presented in the same orientation.

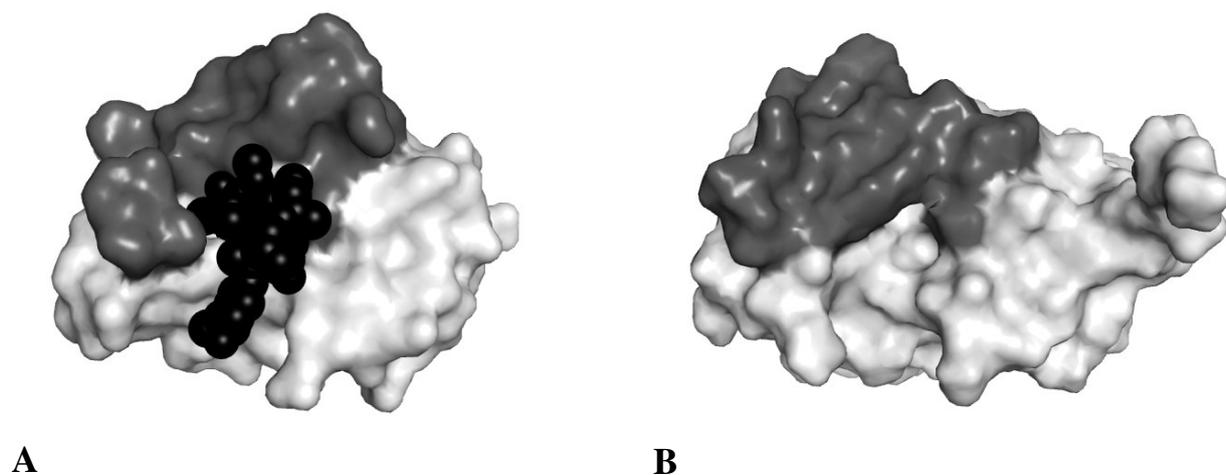

Figure 18. (A) Molecular surface of the FKBP12/FK506 complex. The segments of FKBP12 involved in the interaction with CaN, i.e. Lys34-Phe46 and His87-Ile90, are colored in dark gray. The FK506 molecule is represented as black spheres. (B) Molecular surface of FKBP38³⁵⁻¹⁵³, in the same orientation as the FKBP12/FK506 complex. The segments Thr78-L86 and Arg127-Tyr130, equivalent to those of FKBP12 interacting with CaN, are represented in dark gray.

3.3. Interaction of FKBP38³⁵⁻¹⁵³ with Ca²⁺ and Mg²⁺

During the study of the interaction between FKBP38³⁵⁻¹⁵³ and both CaM forms (see section 3.4), the ¹H/¹⁵N-HSQC spectra of ¹⁵N-labelled FKBP38³⁵⁻¹⁵³ were collected under two different conditions, namely 20 mM NaH₂PO₄ (pH 6.8) for the study of the interaction with apo-CaM as well as 10 mM MES, 100 mM KCl and 6 mM CaCl₂ (pH 6.8) for the study of the interaction

with holo-CaM. The $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of FKBP38³⁵⁻¹⁵³ does not change significantly with the buffer conditions, except for prominent shifts of the amide resonances in the segment comprising residues Leu90-Ile96, which forms the $\beta\text{C}-\alpha\text{1}$ loop. As this part of the protein is essentially negatively charged due to the presence of the residues Asp92, Asp94 and Asp100 (Figure 19), these shift changes suggest the presence of an interaction site for calcium in this region of FKBP38³⁵⁻¹⁵³.

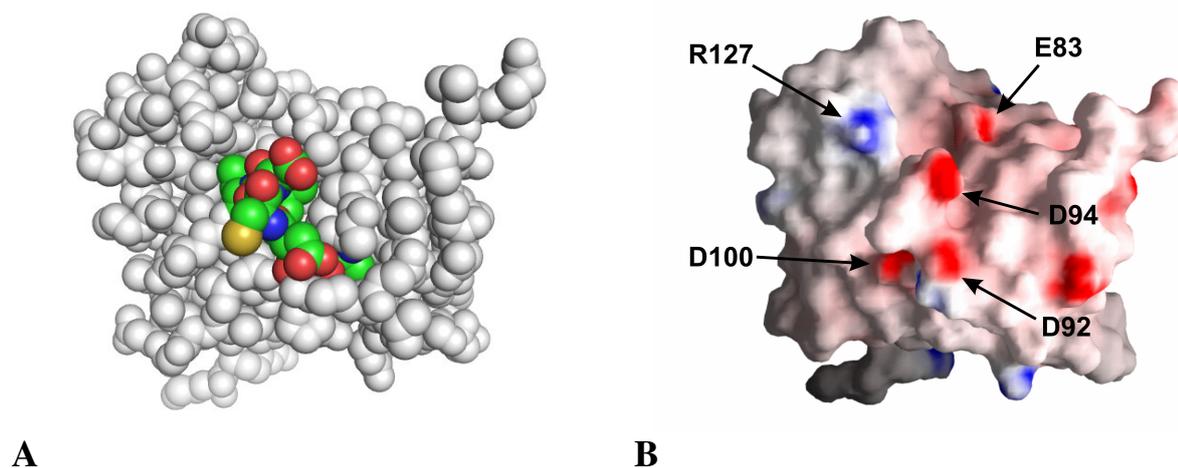

Figure 19. (A) Atomic model of FKBP38³⁵⁻¹⁵³. The amino acids of the segment Leu90-Ile96, which were affected by the presence of Ca^{2+} , are colored according to atom type. (B) Potential energy surface of FKBP38³⁵⁻¹⁵³ in the same orientation. Side-chains of acidic residues possibly relevant for the interaction with Ca^{2+} , as well as those of Glu83 and Arg127, are labelled.

The interaction with Ca^{2+} was confirmed by a titration of the protein (dissolved in a buffer consisting of 10 mM MES, 100 mM KCl, pH 6.8) with CaCl_2 , which resulted in a shift of the same above-mentioned resonances in the $^1\text{H}/^{15}\text{N}$ -HSQC spectrum during the course of the titration (Figure 20). For example, the H^{N} resonance of Asp94 experienced a chemical shift increase of 0.059 ppm upon Ca^{2+} addition and the N resonance of Val95 a decrease of 0.406 ppm. The sequence-specific chemical shift perturbations produced by the addition of Ca^{2+} are summarized in Figure 21A. As a control experiment, a ^{15}N -labelled sample of FKBP12 was titrated with an excess of CaCl_2 , but no significant chemical shift perturbations were observed (Figure 21B). In fact, the highest chemical shift changes are 10-fold lower than those observed in FKBP38³⁵⁻¹⁵³. This is a clear indication that FKBP12 does not interact with Ca^{2+} .

The interaction between FKBP38³⁵⁻¹⁵³ and Ca^{2+} was also detected in the 1D ^1H -NMR spectrum of FKBP38³⁵⁻¹⁵³, where the resonances belonging to H^{N} of Gly91 (displaying a very broad signal in the $^1\text{H}/^{15}\text{N}$ -HSQC spectrum) and $\text{H}^{\gamma 2}$ of Val95 display noticeable chemical shift changes upon addition of Ca^{2+} (Figure 22). Another physiologically relevant ion, Mg^{2+} , was found to interact with FKBP38³⁵⁻¹⁵³ in the same manner, as its addition to FKBP38³⁵⁻¹⁵³ produces the same effects

as Ca^{2+} in the 1D ^1H -NMR spectrum of the protein (Figure 22).

Figure 20. Superposition of a section from the $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of FKBP38³⁵⁻¹⁵³, showing shifts of certain backbone amide resonances during the titration with Ca^{2+} . The spectra in red, cyan and blue correspond to Ca^{2+} concentrations of 0, 3.7 and 7.3 mM, respectively.

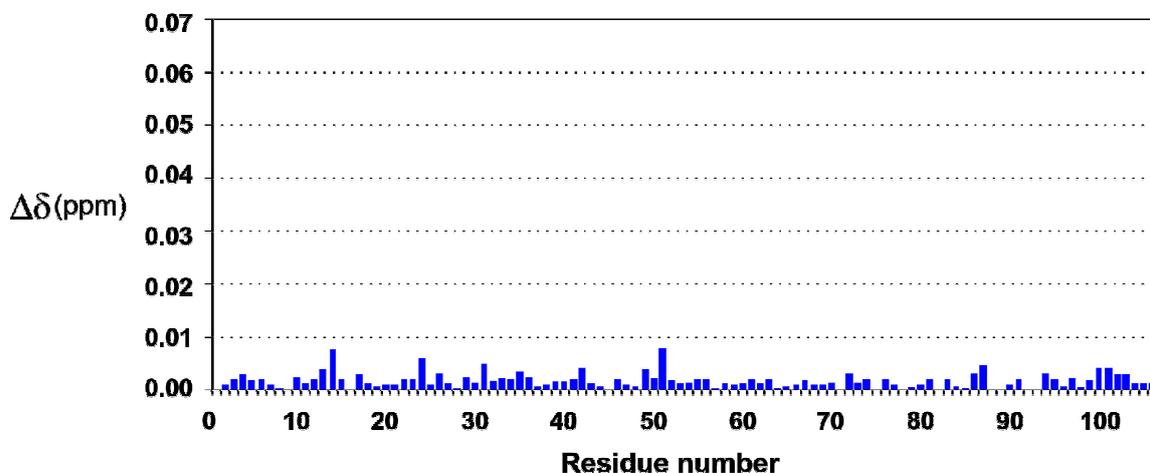

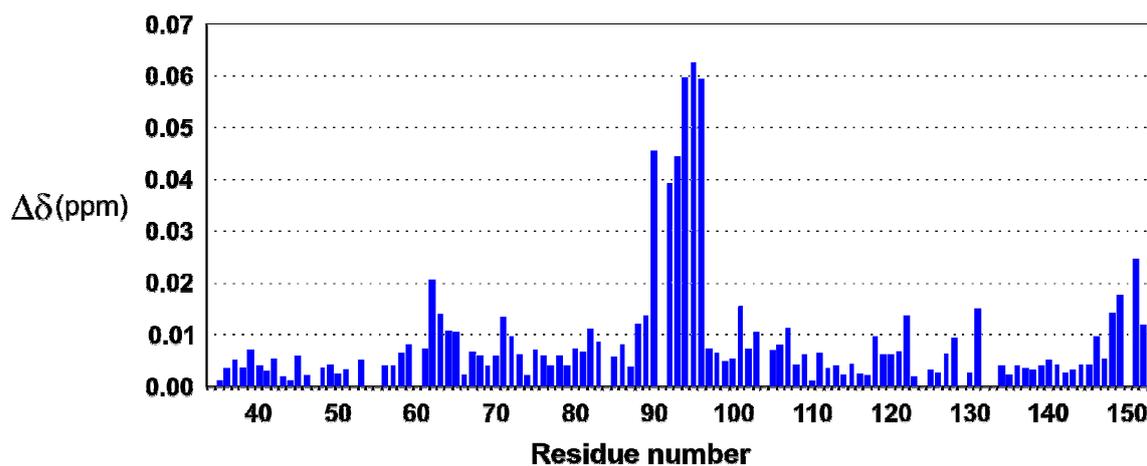

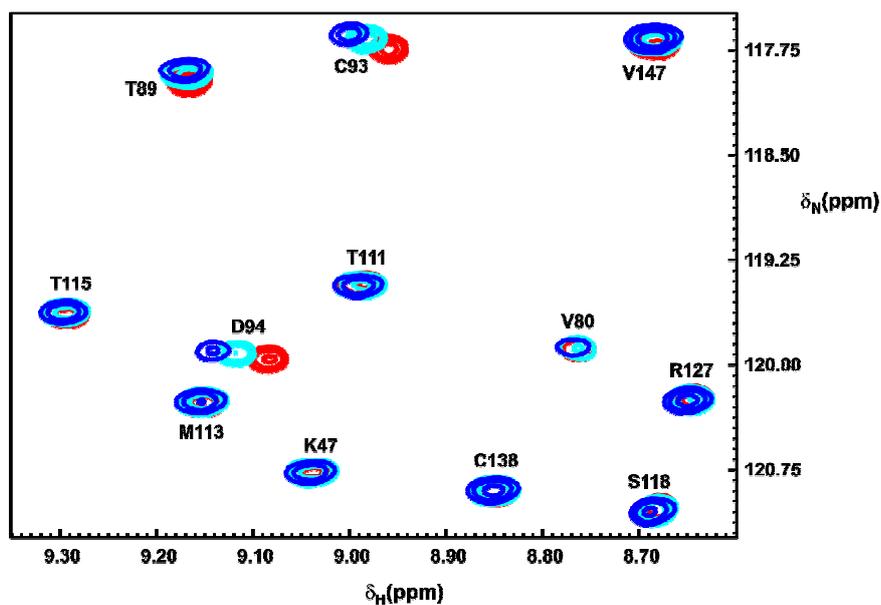

Figure 21. (A) Chemical shift perturbations produced by the addition of 7.3 mM CaCl_2 to a 0.4 mM solution of FKBP38³⁵⁻¹⁵³. (B) Control experiment with FKBP12 under identical conditions.

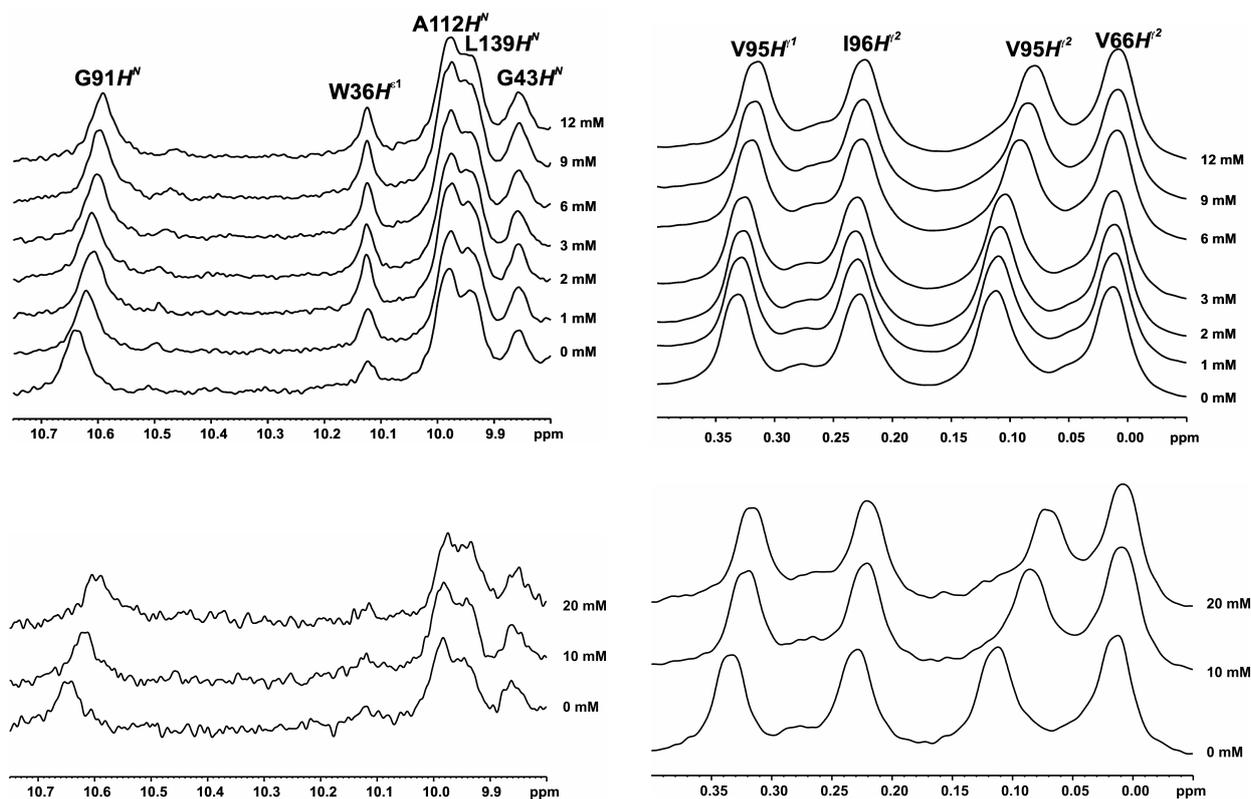

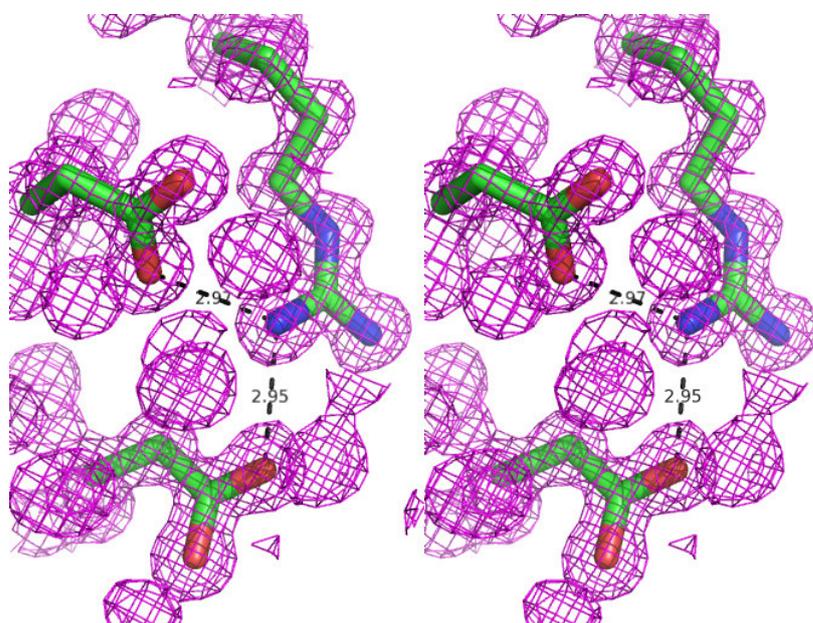

Figure 22. Sections from the 1D ^1H -NMR spectrum of FKBP38³⁵⁻¹⁵³, showing the shift of certain amide (Gly91H^N, left) and methyl (V95H², right) protons during the course of titration with either CaCl₂ (upper panel) or MgCl₂ (lower panel).

Although the chemical shift perturbation data indicated a surface-accessible region with 2 or 3 possible Ca²⁺-coordinating groups (Asp92, Asp94 and Asp100) as interaction site, the precise structural arrangement between FKBP38³⁵⁻¹⁵³ and the divalent cation could not be determined by NMR. The protein was therefore crystallized in a buffer containing CaCl₂. A high quality X-ray structure of FKBP38³⁵⁻¹⁵³ was subsequently obtained with a resolution of 1.05 Å, but no Ca²⁺ ions were found to be bound to the protein. However, the negatively-charged side-chains of Asp92 and Asp94, both part of the loop that displayed chemical shift changes upon Ca²⁺ addition, showed hydrogen-bond contacts to the positively-charged guanidinium group of Arg34 from a neighboring FKBP38³⁵⁻¹⁵³ molecule in the crystal (Figure 23). Apparently, this arrangement leads to an alternative charge compensation that could mimic the electrostatic interactions of the Asp92 and Asp94 side-chains with Ca²⁺.

Fluorescence spectroscopy and isothermal titration calorimetry (ITC) experiments have also confirmed the interaction of Ca²⁺ and Mg²⁺ with FKBP38³⁵⁻¹⁵³ (Dr. Frank Edlich, unpublished results). Fluorescence spectroscopy measurements showed a reduction of the fluorescence intensity of FKBP38³⁵⁻¹⁵³ upon addition of either CaCl₂ or MgCl₂. Moreover, titrations with CaCl₂, MgCl₂ and KCl, carried out with fluorescence detection, clearly showed a higher binding

affinity of FKBP38³⁵⁻¹⁵³ for Ca²⁺ than for Mg²⁺, yet no detectable interactions with K⁺. ITC experiments with Ca²⁺ and FKBP38³⁵⁻¹⁵³ revealed the formation of a 1:1 complex, with a K_D of 17 ± 3 μM, which is close to the range of Ca²⁺ concentrations found in most cells (0.1 to 10 μM). This might allow in case of extremely high local Ca²⁺ concentrations - as for example after Ca²⁺ release by the endoplasmic reticulum - that this FKBP domain senses the Ca²⁺ stimuli. Certainly, the binding of Ca²⁺ to FKBP38³⁵⁻¹⁵³ is rather weak, which explains why it was not observed in the X-ray structure. But the chemical shift perturbation experiments clearly demonstrate an interaction, which could implicate that - in addition to the CaM/Ca²⁺ regulation of FKBP38 - the interaction of Ca²⁺ itself with the FKBP domain of this protein might play a regulatory role in the activity of FKBP38.

Figure 23. Section of the FKBP38³⁵⁻¹⁵³ X-ray structure. Side-chain atoms are represented as stick models colored by atom type, and the electron densities are shown in magenta. The side-chains of residues Asp92 and Asp94 form hydrogen bonds to the side-chain of Arg34 that belong to an adjacent FKBP38³⁵⁻¹⁵³ molecule in the crystal.

Based on the structure of FKBP38³⁵⁻¹⁵³, two different explanations can be envisioned for the regulation of this domain by Ca²⁺. First, a change in the net charge around the active site from -4 to -2 after Ca²⁺-binding, which could affect considerably the binding of charged ligands such as polypeptide chains, probably leading to a negative regulation of the FKBP38 activity when it interacts with positively-charged ligands. On the other hand, it was already mentioned that salt-bridges connecting the side-chains of Asp94 and Glu83 with Arg127 can be formed in FKBP38, possibly leading to the stabilization of a “closed active site”. The binding of Ca²⁺ to the side-chain of Asp94, in a manner similar to that shown in Figure 23, would destabilize these salt-bridges, probably leading to an opening of the active site and thus producing a positive regulation of the FKBP38 activity.

3.4. Interaction of FKBP38³⁵⁻¹⁵³ with calmodulin

The most interesting feature of FKBP38 is its activation upon complex formation with CaM. In addition to the Ca²⁺-dependent interaction of FKBP38 with CaM, which is due to the putative CaM-binding site located at the end of the TPR domain, a Ca²⁺-independent interaction between the catalytic FKBP domain and CaM has been identified, which causes an activation of the FKBP domain (Edlich et al., in preparation).

In order to obtain structural information about the complex between FKBP38³⁵⁻¹⁵³ and CaM, 2D ¹H/¹⁵N-HSQC spectra comparing the free and the complexed state of each protein were collected. Employing ¹⁵N-labelled protein samples, changes in the chemical shift values of certain amide resonances, which occur as a result of the addition of a 3-fold excess of the non-labelled binding partner, reveal the residues involved in (or affected by) the complex formation.

Once these residues are determined, a docking calculation of the protein/protein complex can be performed, using the program HADDOCK (Dominguez et al., 2003). This program overcomes the hurdle posed by the lack of specific intermolecular distance restraints, as it transforms the residues at each contact surface into a set of Ambiguous Interaction Restraints (AIRs) that drives the docking calculation towards a final structure where the contact surfaces of both proteins face each other. The structures with the lowest intermolecular energies (i.e. the sum of van der Waals, electrostatic and AIR energy terms) are selected as output of the structure calculation. This docking approach is especially well suited for transient protein/protein interactions (like the ones presented here), where the collection of intermolecular NOEs can be extremely difficult or even impossible.

3.4.1. NMR assignments of the backbone amide resonances of apo- and holo-calmodulin

A reliable backbone amide resonance assignment is a fundamental precondition for a successful chemical shift perturbations study. For both forms of CaM, no previous resonance assignments under the conditions selected for the present study had been reported in the literature. However, ¹H, ¹³C and ¹⁵N resonance assignments of apo-CaM from *Xenopus laevis* (african frog) at 23 °C and pH 6.3 (kindly provided by Dr. Ad Bax; ¹H and ¹⁵N assignments reported by Tjandra et al., 1995) and of holo-CaM from *Drosophila melanogaster* at 47 °C and pH 6.3 (Ikura et al., 1990) were available. These assignments could be used as starting points to determine the chemical shifts of the amide resonances of apo- and holo-CaM at the here applied conditions. This was achieved with ¹⁵N-labelled protein samples by using the classical assignment strategy (Wüthrich,

1986).

In the case of apo-CaM, the relatively small differences in the experimental conditions and the fact that the human CaM is 100% identical to that of *Xenopus laevis* facilitated the assignment of the amide resonances, resulting in a set of chemical shifts very similar to the one reported by Tjandra (Table 5, Figure 24). A systematic ~0.4 ppm up-field shift of the ¹⁵N resonances was found, possibly arising from (i) the different reference systems used for the chemical shifts and (ii) the difference in temperature. Only the resonances belonging to the segment Asp22-Ile27 were not found in the present spectra, due to their special dynamic behavior (Tjandra et al., 1995). Additional resonances arose from the additionally introduced C-terminal His-tag used. The close agreement of this apo-CaM assignment with the one previously reported by Tjandra furthermore confirms that CaM is free of Ca²⁺ under the experimental conditions chosen in the present study.

Table 5. ¹H and ¹⁵N backbone amide resonance assignments (in ppm) of apo-CaM at 298 K and pH 6.8.

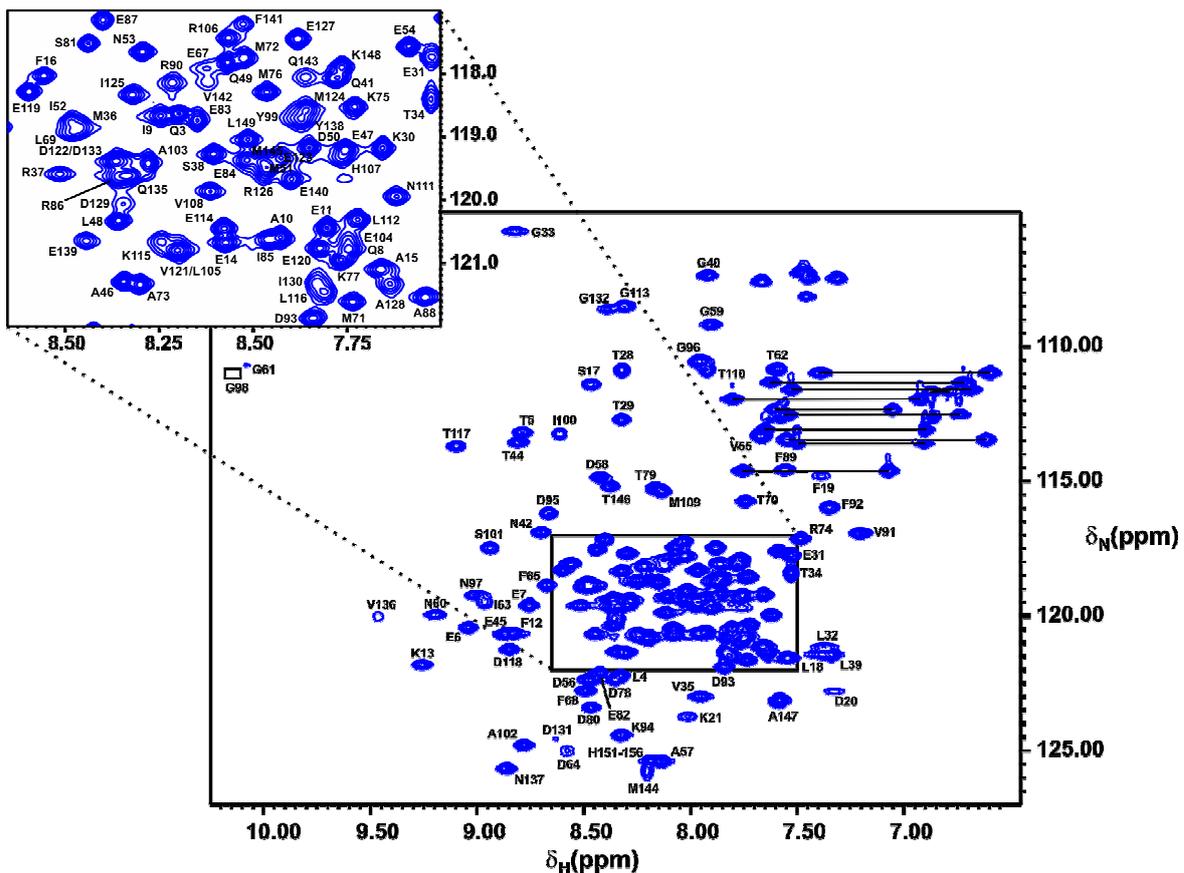

Figure 24. Two-dimensional $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of apo-CaM recorded at 500.13 MHz. The sequence-specific assignment of the backbone amide resonances is indicated. Boxes mark signals that appear below the plot level.

In case of the holo-CaM assignment, the combination of (i) a larger temperature difference, (ii) the presence of three amino-acids substitutions (Y99F, D129N and Q143T) and (iii) the presence

of the above-mentioned additional His-tag produced some major chemical shift differences to the previous reported assignment (Ikura et al., 1990). Nevertheless, nearly all backbone amide resonances could be assigned (Table 6, Figure 25).

Table 6. ^1H and ^{15}N resonance assignments (in ppm) of holo-CaM at 298 K and pH 6.8.

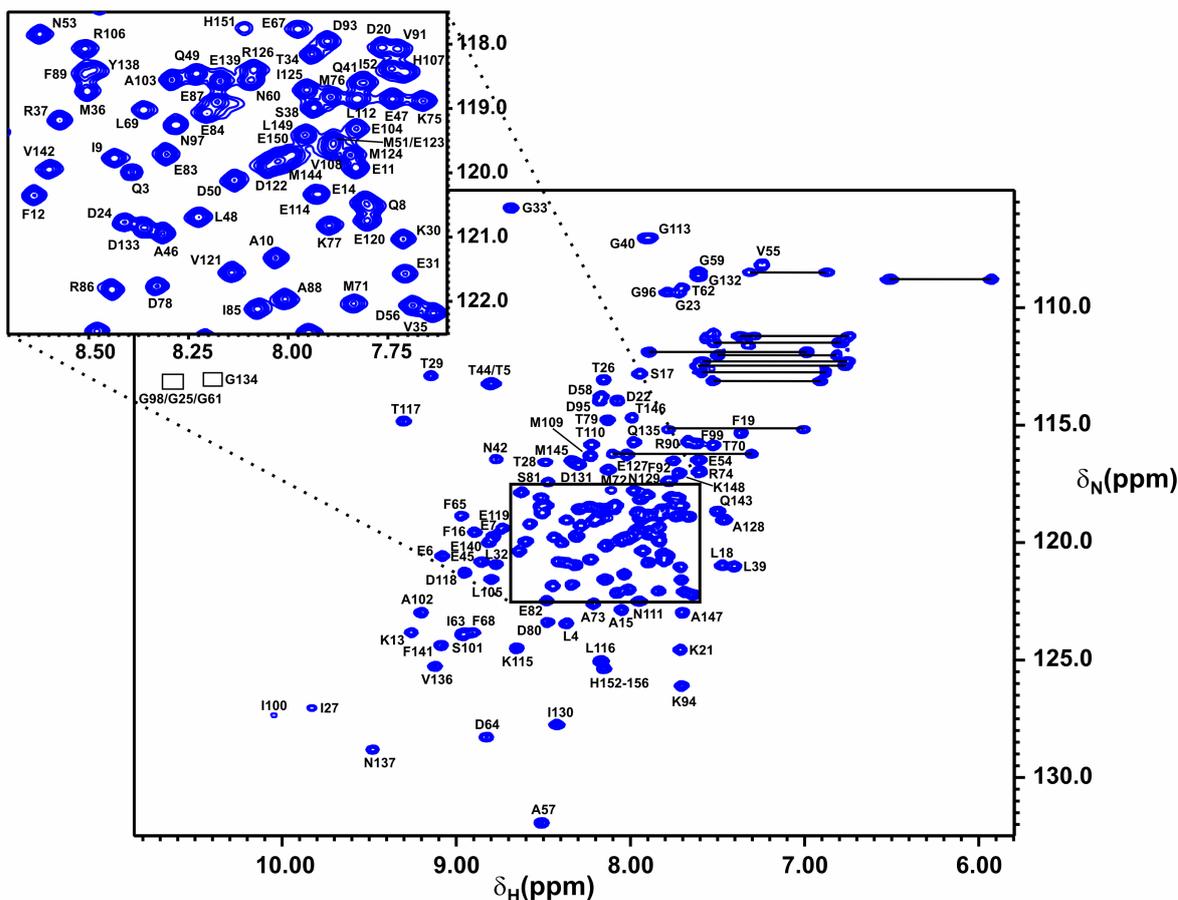

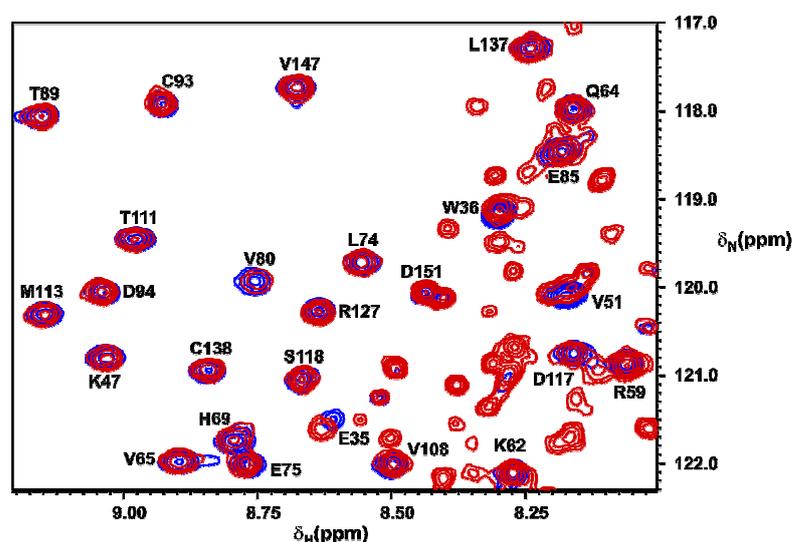

Figure 25. Two-dimensional $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of holo-CaM recorded at 500.13 MHz. The sequence-specific assignment of the amide resonances is indicated. Boxes mark signals that appear below the plot level.

3.4.2. Interaction of FKBP38³⁵⁻¹⁵³ with apo-calmodulin

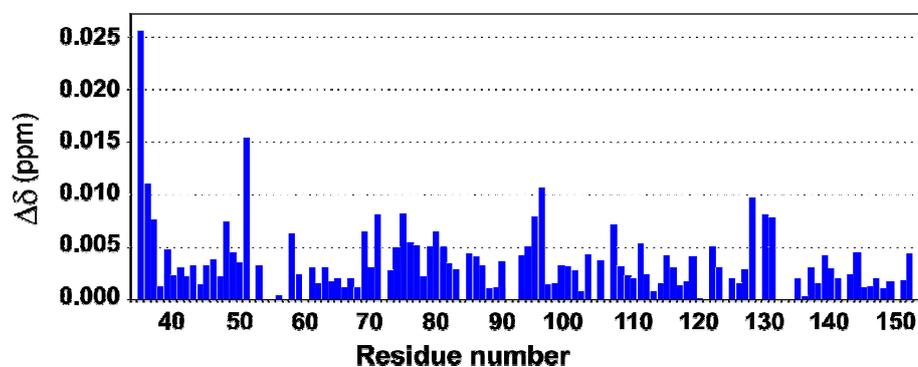

Although the non-labelled binding partner was added in excess to shift the equilibrium toward the complex, the chemical shift perturbations of the amide resonances of ^{15}N -labelled FKBP38³⁵⁻¹⁵³ were rather small upon addition of apo-CaM (Figure 26), as expected for a complex with a relatively low binding constant. The calculated combined chemical shift perturbations $\Delta\delta$ (Figure 27) exhibited an average value of 0.004 ppm, whereas the highest chemical shift perturbation (Glu35) reached 0.026 ppm. Several amide resonances were affected by more than 0.005 ppm, such as the segments Leu74-Gln81 (with the exception of Thr78), which comprises the βC - βD loop, and Ser128-Ile131 (located in the N-terminal part of the long βE - βF loop), as well as the residues His69 and Gln71, which are both located at the outer surface of the βC strand. The majority of these residues form a well-defined surface centered at the βC - βD loop (Figure 28). The most pronounced of these chemical shift changes, however, were found close to the N-

terminus. In particular, the above-mentioned Glu35 together with Trp36, Leu37 and Lys48 seem to be affected by a small change in the orientation of the aromatic Trp36 side-chain. This conclusion is supported by the observation of a 4 nm red-shift and an 8.5% loss of intensity in the fluorescence spectrum of FKBP38³⁵⁻¹⁵³ upon binding to apo-CaM (Edlich et al., in preparation), which is consistent with a change in the local environment of the Trp36 indol ring (the only tryptophan in FKBP38³⁵⁻¹⁵³).

Figure 26. Section from the ¹H/¹⁵N-HSQC spectrum of ¹⁵N-labelled FKBP38³⁵⁻¹⁵³, showing the changes caused in the backbone resonances by the complex formation with apo-CaM. The blue signals correspond to the free form of FKBP38³⁵⁻¹⁵³, while the red signals correspond to the FKBP38³⁵⁻¹⁵³/apo-CaM complex. Additional small sharp signals in the complex spectrum are due to denatured FKBP³⁸⁻¹⁵³.

A

B

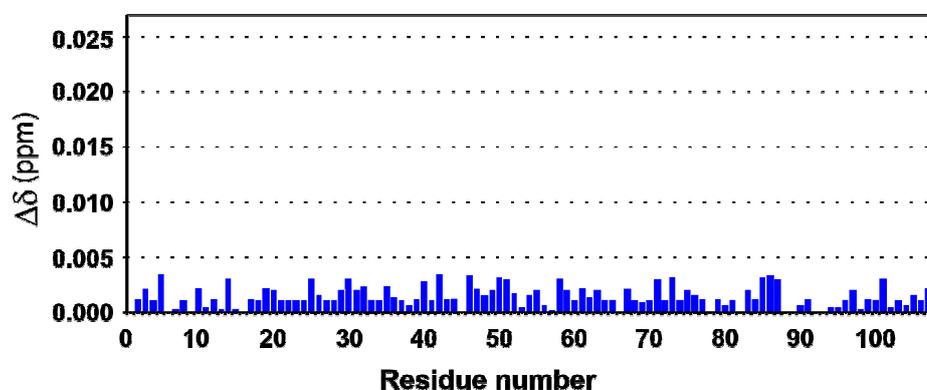

Figure 27. (A) Overview of the combined chemical shift changes ($\Delta\delta$) observed for ¹⁵N-labelled FKBP38³⁵⁻¹⁵³ upon addition of a 3-fold molar excess of apo-CaM. (B) Control experiment with FKBP12 under similar conditions.

The residues Asp94, Val95, Ile96 and Tyr122, also displaying considerable chemical shift changes, are located in the contact region between the loops β E- β F and β D- α 1. Most of them (with exception of Asp94) are not solvent accessible and therefore unlikely to be involved in the direct interaction with apo-CaM. These chemical shift perturbations could be attributed to a secondary binding effect, presumably as a result of a small rearrangement of the long β E- β F loop, which is seemingly directly involved in the interaction (see above). The chemical shift changes observed in the residues Ser58 and Asp107, located at the opposite side of the protein, are most likely secondary effects as well.

Hence, the contact surface thus derived is centered at the β C- β D loop, also comprising parts of the extended β E- β F loop (which blocks the access to the binding site) and the external side of the β -sheet. This result may provide an explanation for the observed activation of this FKBP domain upon complex formation with CaM (Edlich et al., in preparation), as (i) the active site does not seem to be occupied by apo-CaM and (ii) the interaction with the β E- β F loop could produce a change in its conformation that results in an opening of the active site. The secondary effects observed at the β D- α 1 loop, also bordering the active site, support the last hypothesis.

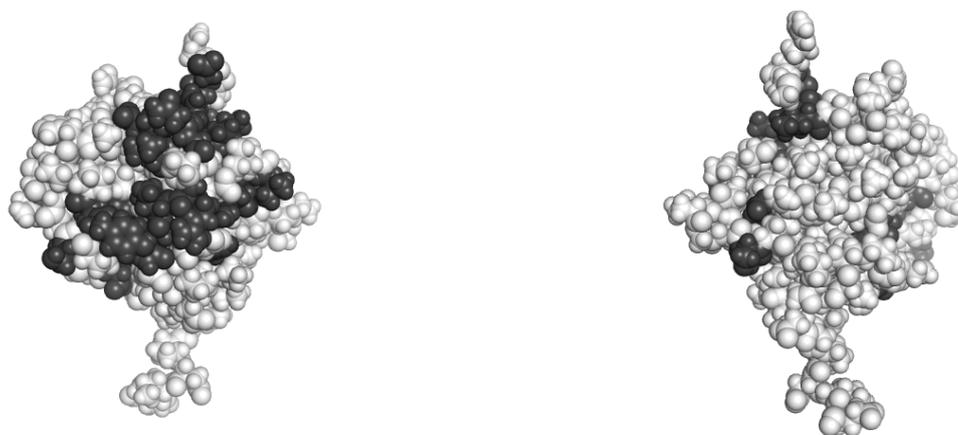

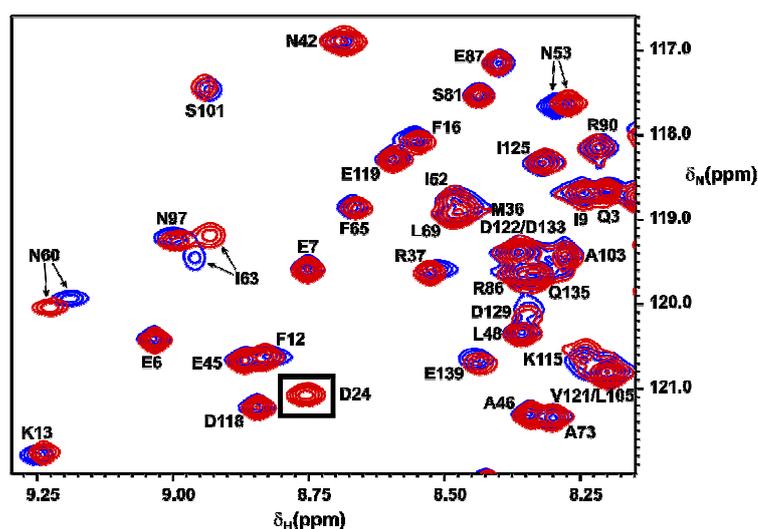

Figure 28. Atomic model of FKBP38³⁵⁻¹⁵³. The residues affected by the interaction with apo-CaM are shown in dark gray.

The complex formation of ¹⁵N-labelled apo-CaM with FKBP38³⁵⁻¹⁵³ produced more pronounced chemical shift perturbations (Figure 29) than the reverse experiment. More precisely, the calculated combined chemical shift perturbations $\Delta\delta$ (Figure 30) exhibit an average value of 0.009 ppm, more than twice as that observed for FKBP38³⁵⁻¹⁵³, while the highest chemical shift perturbation of 0.054 ppm was found for Ile63. The most pronounced chemical shift perturbations (i.e. those higher than 0.02 ppm) were all observed in the N-terminal domain of apo-CaM, especially in the segment Asn60-Asp64, which is part of the central loop of the second EF-hand motif (Figure 31). Furthermore, the resonances that correspond to the segment

comprising residues Asp22-Ile27, which is part of the central loop of the first EF-hand motif, were observed only in the complexed form (Figures 29 and 30), indicating a change in the backbone dynamics of these resonances as a result of the binding process. This may be explained by a reduction of (i) the backbone dynamics or (ii) the amide hydrogen exchange rate of these residues upon binding to FKBP38³⁵⁻¹⁵³. Increased backbone dynamics within the segment Lys21-Gly25 (characterized by higher than normal amplitudes for the rapid internal motions of the backbone atoms, $S^2 < 0.8$) as well as a fast amide hydrogen exchange ($\tau_{\text{exch}} < 200$ s) were already reported for these residues based on NMR relaxation studies of apo-CaM (Tjandra et al., 1995; Kuboniwa et al., 1995). The interaction of the first EF-hand motif with FKBP38³⁵⁻¹⁵³ is corroborated by the observation of considerable chemical shift perturbations of other signals that belong to this loop, namely Lys21 and Thr29. Interestingly, the affected central loops of both EF-hand motifs are spatially very close; in fact, parts of them (Thr62-Ile63 and Thr26-Ile27) even form a small antiparallel β -sheet.

Figure 29. Section from the $^1\text{H}/^{15}\text{N}$ -HSQC spectrum of ^{15}N -labelled apo-CaM, showing the changes in the backbone resonances caused by the complex formation with FKBP38³⁵⁻¹⁵³. The blue signals correspond to the free form of apo-CaM, while the red signals correspond to the FKBP38³⁵⁻¹⁵³/apo-CaM complex. The resonance belonging to Asp24, shown in a black box, is visible only in the spectrum of the FKBP38³⁵⁻¹⁵³/apo-CaM complex.

Other residues of the N-terminal apo-CaM domain also showed significant chemical shift perturbations upon complex formation with FKBP38³⁵⁻¹⁵³, in particular Ser17, Phe19, Thr34, Asn53 and Ala57, which are located in the helices A (Ser17 and Phe19), B (Thr34) and C (Asn53 and Ala57), respectively, and thus fairly close to the two loops affected by the interaction with FKBP38³⁵⁻¹⁵³. Nevertheless, these residues apparently play only a minor role (or even none) in the interaction, since they are located in peripheral positions at the protein surface compared to the rest of the affected amino acids. Hence, the region involved in the interaction with FKBP38³⁵⁻¹⁵³ should be centered at the central loops of both EF-hand motifs of the N-terminal apo-CaM domain.

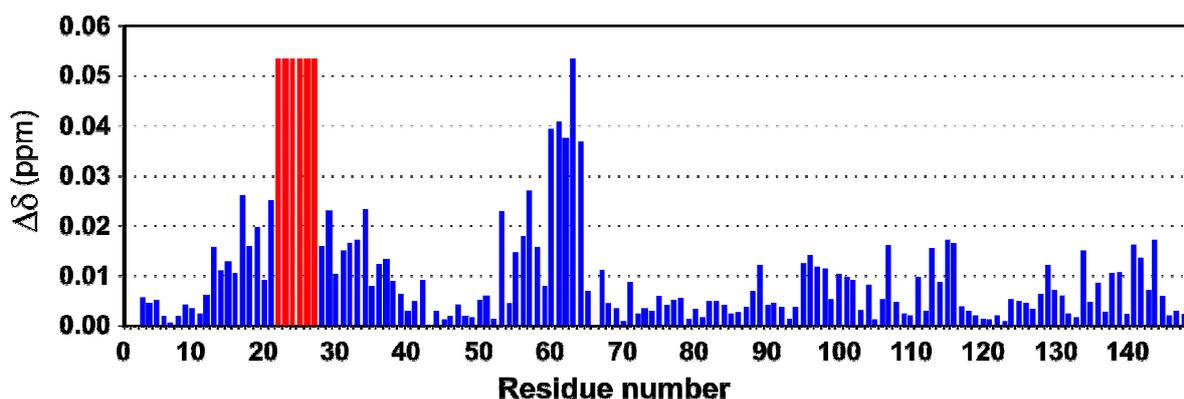

Figure 30. Overview of the combined chemical shift changes ($\Delta\delta$) observed for ^{15}N -labelled apo-CaM upon addition of a 3-fold molar excess of FKBP38³⁵⁻¹⁵³. Residues showing changes in the backbone dynamics (i.e. signals observed only in the complexed form) were arbitrarily assigned with the maximal chemical shift perturbation value (represented by red bars).

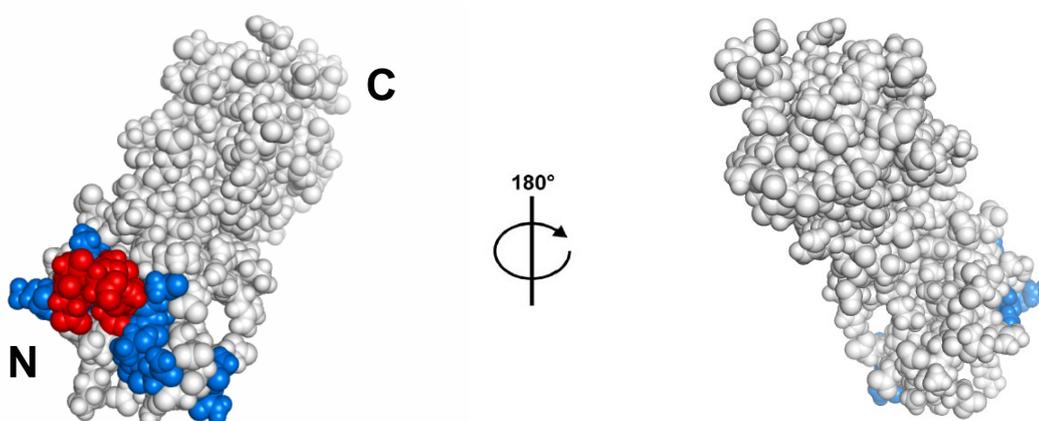

Figure 31. Atomic model of apo-CaM, showing the surface interacting with FKBP38³⁵⁻¹⁵³. Residues displaying chemical shift perturbations higher than 0.02 ppm after addition of FKBP38³⁵⁻¹⁵³ are colored in blue. The residues of the segment Asp22-Ile27, which experience a change in backbone dynamics upon complex formation, are highlighted in red.

This interaction between the N-terminal domains of FKBP38 and CaM is in good agreement with recently performed studies (Edlich et al., in preparation), which showed that the CaM N-terminal domain (CaM¹⁻⁷⁵) is sufficient to (i) increase the PPIase activity of FKBP38³⁵⁻¹⁵³ and (ii) to activate FKBP38 for its interaction with Bcl-2 independently of the presence or absence of Ca^{2+} .

A comparison of the amino acid sequences of both CaM domains (Figure 32A) provides an explanation for their different affinity for FKBP38³⁵⁻¹⁵³. In the N-terminal CaM domain, the side-chains of residues Thr26 and Thr62 form the outer part of the short β -sheet that connects both EF-hand loops. In the C-terminal CaM domain, on the other hand, the corresponding positions are occupied by the more bulky side-chains of Tyr99 and Gln135. These variations thus produce different molecular surfaces in this region of the CaM domains (Figure 32B): (i) in the N-terminal domain a surface with a small cavity, capable to interact with FKBP38³⁵⁻¹⁵³, and (ii) in

the C-terminal domain a surface lacking this cavity, apparently rendering it unsuitable for the interaction with FKBP38³⁵⁻¹⁵³.

3.4.3. Interaction of FKBP38³⁵⁻¹⁵³ with holo-calmodulin

As mentioned already in section 2.2.4.2.3., the titration of ¹⁵N-labelled FKBP38³⁵⁻¹⁵³ with holo-CaM produced no results due to the denaturation of FKBP38³⁵⁻¹⁵³ during the experiment. However, ¹⁵N-labelled holo-CaM was successfully complexed with FKBP38³⁵⁻¹⁵³. The chemical shift changes obtained were even larger than those found in the corresponding experiment with apo-CaM (Figure 33), as an average value of 0.031 ppm was obtained for the combined chemical shift perturbations $\Delta\delta$, with a maximal value of 0.185 ppm for Glu68 (Figure 34). Moreover, several signals of the N-terminal holo-CaM domain (e.g. Phe19 and Thr70) (Figures 33 and 34) disappeared upon complex formation due to extensive line-broadening. This change on the backbone relaxation could originate from (i) the presence of an additional relaxation process in the complexed state of holo-CaM or (ii) a change in the time scale of a conformational interconversion that may lead to an increase of the relaxation rates for these resonances.

All residues undergoing either significant chemical shift perturbations (i.e. those larger than 0.04 ppm) or changes of their backbone relaxation upon complex formation are located in the N-terminal holo-CaM domain. Again, pronounced effects were found in the central loops of both

EF-hand motifs of this domain, which are therefore considered as the region of the protein directly in contact with FKBP38³⁵⁻¹⁵³ (Figure 35).

Figure 33. Section from the ¹H/¹⁵N-HSQC spectrum of ¹⁵N-labelled holo-CaM, showing the changes produced in the backbone resonances by the complex formation with FKBP38³⁵⁻¹⁵³. The red signals correspond to the free form of holo-CaM, while the blue signals correspond to the FKBP38³⁵⁻¹⁵³/holo-CaM complex. The resonance belonging to Thr70, shown in a black box, is visible only in the spectrum of the free form.

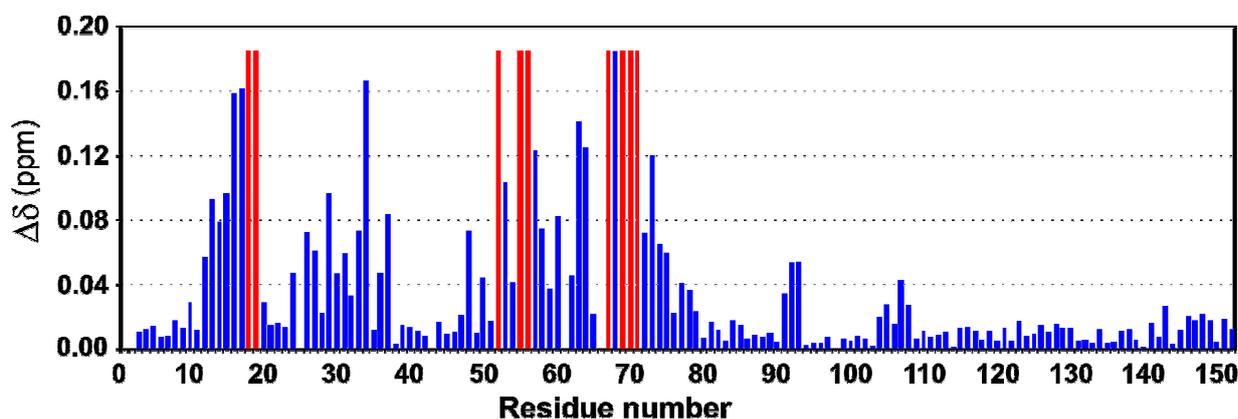

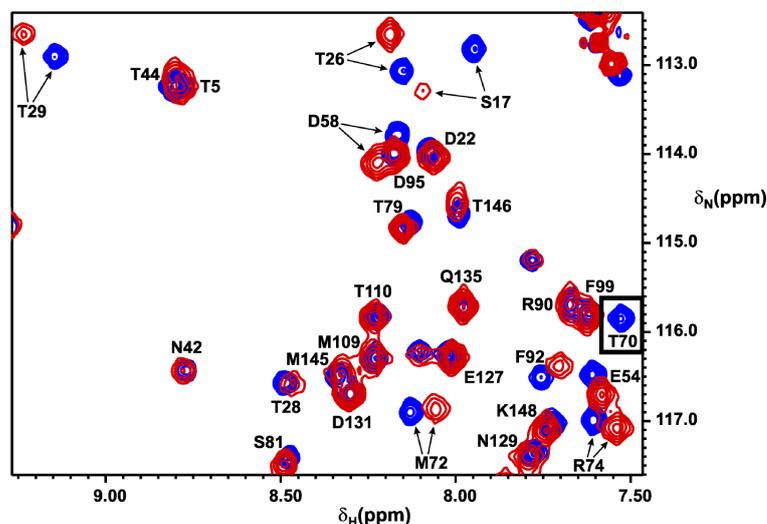

Figure 34. Overview of the combined chemical shift changes ($\Delta\delta$) observed for ¹⁵N-labelled holo-CaM upon addition of a 3-fold molar excess of FKBP38³⁵⁻¹⁵³. Residues showing changes in the backbone dynamics (i.e. signals with extensive line-broadening) upon complex formation were assigned the maximal chemical shift perturbation value (represented by red bars).

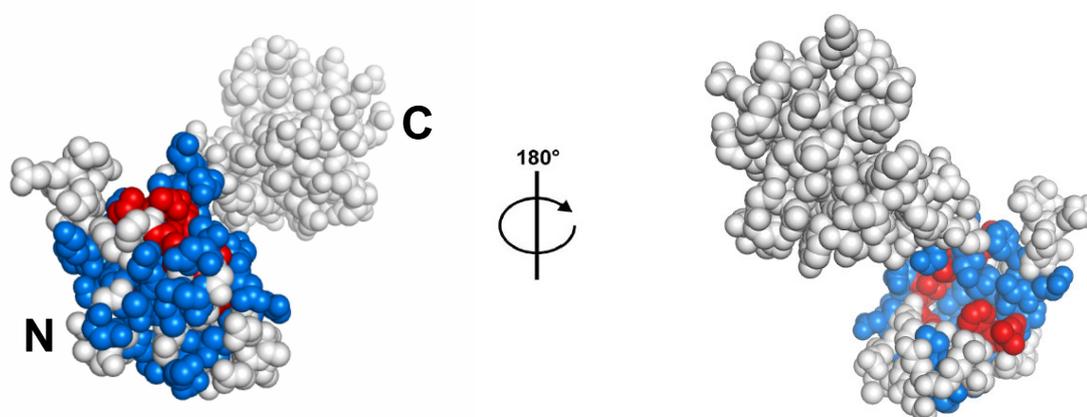

Figure 35. Atomic model of holo-CaM that shows the surface which interacts with FKBP38³⁵⁻¹⁵³. Residues displaying chemical shift perturbations higher than 0.04 ppm due to the presence of FKBP38³⁵⁻¹⁵³ are colored in blue. Residues undergoing a change in backbone dynamics upon complex formation are highlighted in red.

Nevertheless, additional perturbation effects of considerable magnitude were also found in all four helices of the N-terminal domain, always at the ends that are closer to the central loops. These residues, however, are either not surface accessible (e.g. Phe16, Gly33, Ile52, Asp56 and Phe68) or can not easily contribute to the formation of a more reasonable interacting surface as that featured by the central loops of the EF-hand motifs. Therefore, these effects at the helices are considered as secondary effects, which propagate through the helices as the result of the FKBP38³⁵⁻¹⁵³ interaction with the surface defined by both central loops.

As in the case of apo-CaM, the replacement of the residues Thr26 and Thr62, which are located at the center of the contact region of the N-terminal holo-CaM domain, with Tyr99 and Gln135 in the C-terminal domain seems to be the reason for the higher affinity of FKBP38³⁵⁻¹⁵³ for the N-terminal holo-CaM domain. Both side-chains, especially that of Tyr99, protrude from the surface of the C-terminal holo-CaM domain (Figure 36), producing an uneven surface instead of a flat or slightly caved surface in the N-terminal domain.

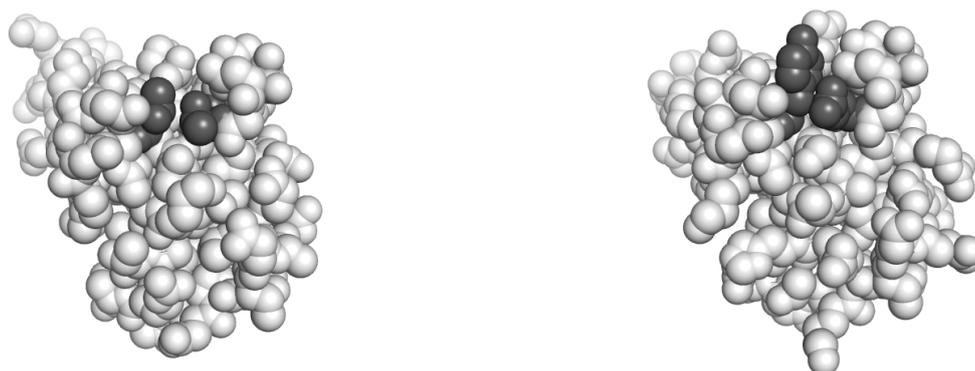

Figure 36. Atomic models of the N-terminal (**left**) and C-terminal (**right**) domains of holo-CaM. The side-chains of residues Thr26 and Thr62 in the N-terminal domain as well as the corresponding residues Tyr99 and Gln135 in the C-terminal domain are highlighted in dark gray.

3.4.4. Comparison of the interactions of FKBP38³⁵⁻¹⁵³ with apo- and holo-calmodulin

The chemical shift perturbations calculated from the titrations of ¹⁵N-labelled apo- and holo-CaM with FKBP38³⁵⁻¹⁵³ are presented in Figure 37. Remarkably, in both forms of CaM only residues belonging to the N-terminal domain were affected by the complex formation with FKBP38³⁵⁻¹⁵³. Moreover, the affected residues can be grouped into two segments (Lys13-Arg37 and Asn53-Asp64), which are centered at the EF-hand loops of the N-terminal CaM domain. Interestingly, although these protein segments are responsible for the Ca²⁺-binding in this CaM domain, their conformation does not change considerably between the apo- and the holo-form (Figure 38), as reflected by a backbone RMSD of 2.09 Å between this region (i.e. the segments Lys13-Glu31 and Asp58-Asp64) of the apo- and holo-CaM structures. On the other hand, the

amide resonances corresponding to the segment Ser38-Met51, the one displaying the most pronounced structural variation upon Ca^{2+} -binding, show no significant shift effects as a result of the complex formation with FKBP38³⁵⁻¹⁵³ (with the single exception of Leu48 in holo-CaM). The fact that the regions of CaM which are involved in the interaction with FKBP38³⁵⁻¹⁵³ essentially present the same backbone fold could provide an explanation why the interaction between the N-terminal CaM domain and FKBP38³⁵⁻¹⁵³ is Ca^{2+} -independent.

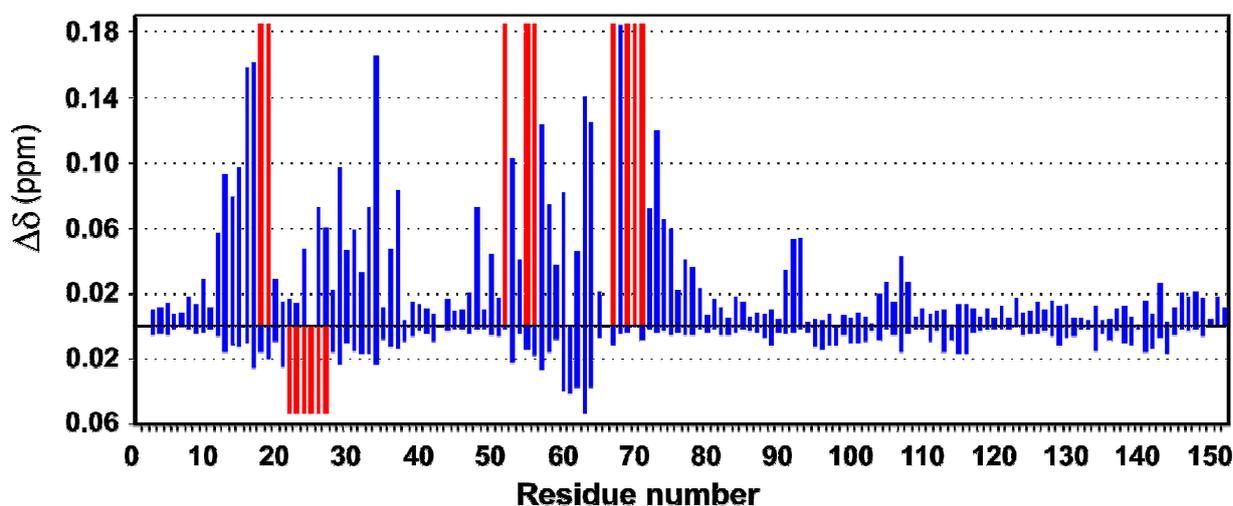

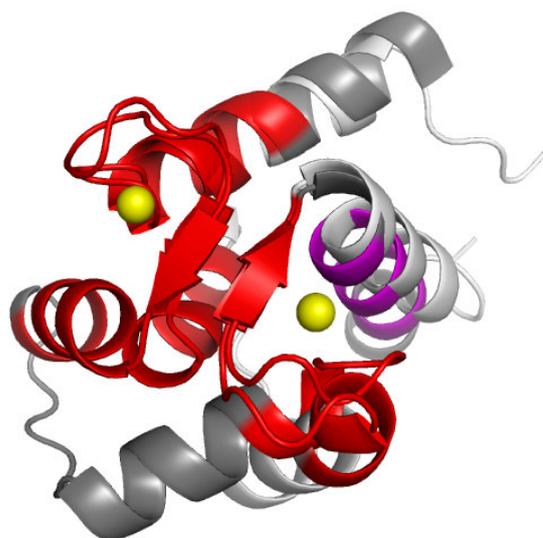

Figure 37. Comparison of the combined chemical shift changes ($\Delta\delta$) observed for ^{15}N -labelled apo- (**lower part**) and holo-CaM (**upper part**) upon addition of a 3-fold molar excess of FKBP38³⁵⁻¹⁵³. Residues undergoing changes in the backbone dynamics upon complex formation were assigned the maximal chemical shift perturbation value (represented by red bars).

Nevertheless, a few differences were observed between the experiments with apo- and holo-CaM. First, the magnitude of the chemical shift changes produced by the complex formation with FKBP38³⁵⁻¹⁵³ was about 3-fold higher in the case of holo-CaM. Moreover, additional residues (e.g. Ile52 and especially the segment Glu67-Lys75) were affected by the interaction of holo-CaM with FKBP38³⁵⁻¹⁵³. An explanation for these observations might be a more pronounced conformational disturbance in holo-CaM during the binding event, compared to apo-CaM.

In addition, a different response in the relaxation of certain resonances upon binding to FKBP38³⁵⁻¹⁵³ was found between apo- and holo-CaM. In the case of apo-CaM, the signals of the resonances corresponding to the segment Asp22-Lys27 were observed only in the complexed form, whereas in holo-CaM several resonances belonging to residues in the helices A, C and D were detected only in the free form. The origin of these effects could be associated with the differences in backbone dynamics between both forms of CaM (i.e. a more flexible backbone in apo-CaM than in holo-CaM) (Kuboniwa et al. 1995, Tjandra et al. 1995, Barbato et al. 1992).

Figure 38. Backbone superposition of apo-CaM (white ribbon) and holo-CaM (gray ribbon). The regions affected by the interaction with FKBP38³⁵⁻¹⁵³ are highlighted in red. The segment Glu67-Lys75, which is affected only in holo-CaM, is represented in magenta. The Ca²⁺ atoms of holo-CaM are shown as yellow spheres.

3.4.5. Three-dimensional structures of the FKBP38³⁵⁻¹⁵³/CaM complexes

For the calculation of the three-dimensional structures of the apo- and holo-CaM/FKBP38³⁵⁻¹⁵³ complexes with HADDOCK, the information obtained from the NMR titration experiments (i.e. residues experiencing chemical shift changes or dynamic effects upon complex formation) was converted into AIRs. The cut-offs for the combined chemical shift changes ($\Delta\delta_{\text{cut-off}}$) were selected arbitrarily, but always at values higher than the average chemical shift changes ($\Delta\delta_{\text{ave}}$) of each data set. A surface accessibility of at least 20%, calculated for all atoms of the residues with the program NACCESS (Hubbard and Thornton, 1993), was introduced as an additional precondition. The residues complying with both requirements were selected as active AIRs. Furthermore, residues directly adjacent to other that represent active AIRs were selected as passive AIRs, if they are surface accessible as well. The result of this selection process was a well-defined interaction surface, composed of active and passive AIR residues, which could be used for the docking calculation with HADDOCK. The transformation of a set of chemical shift perturbations into an interaction surface for HADDOCK calculations is exemplified for FKBP38³⁵⁻¹⁵³ in Figure 39.

3.4.5.1. Three-dimensional structure of the FKBP38³⁵⁻¹⁵³/apo-CaM complex

In the case of FKBP38³⁵⁻¹⁵³, a $\Delta\delta_{\text{cut-off}}$ of 0.005 ppm was chosen, which is slightly higher than the $\Delta\delta_{\text{ave}}$ of 0.004 ppm. The residues Glu35, Trp36, Leu37, Lys48, Leu51, Ser58, His69, Gln71, Leu74, Glu75, Asn76, Gly77, Arg79, Val80, Gln81, Asp94, Val95, Ile96, Asp107, Thr111,

Tyr122, Ser128, Tyr130 and Ile131 all showed $\Delta\delta$ values above this cut-off. Residues Glu75, Asn76, Gly77 and Arg79, all surface accessible and defining the central region of the interaction surface, were selected as active AIRs. On the other hand, residues Val80, Val95, Ile96, Tyr122 and Ile131, which are not surface accessible, as well as Leu37, Leu51, Ser58, His69, Gln81, Asp94, Asp107 and Thr111, which are located either at the opposite side of the protein or too peripheral relative to the rest in the molecular surface, were rejected as AIRs. The rest of these residues were selected as passive AIRs for the following reasons: (i) Glu35, Trp36, Lys48, Gln71, Ser128 because of their location at the borders of the interaction surface; (ii) Leu74, as a consequence of its rather low surface accessibility and (iii) Tyr130, since its use as active AIR led to a presumably incorrect structural arrangement, were the side-chains of Tyr130 and Lys30 (from CaM) point towards each other in order to fulfill the imposed constraint. Residues Thr78, Pro129, Pro132 and Ala136, which are also part of the interaction surface, were introduced as additional passive AIRs according to the criteria described above (Figure 39, Table 7).

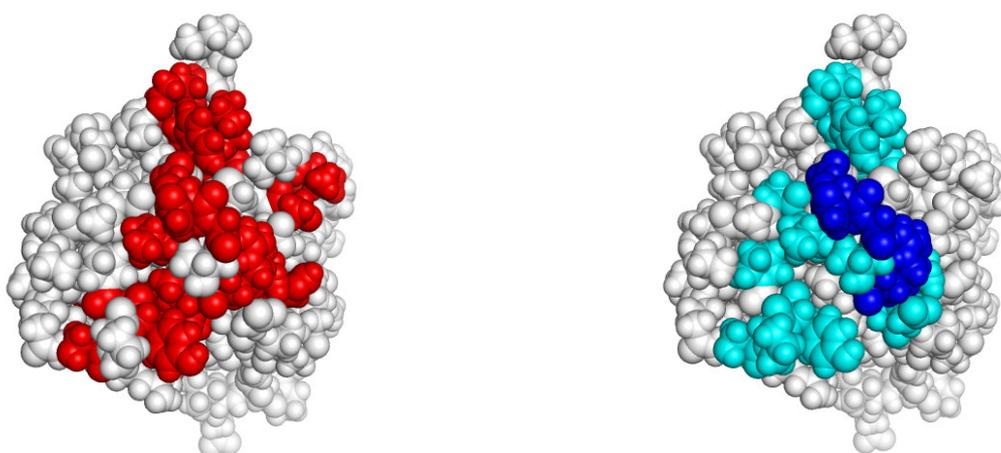

Figure 39. Atomic models of FKBP38³⁵⁻¹⁵³ that show (A) the residues affected by the interaction with apo-CaM, and (B) the residues selected as active (blue) and passive (cyan) AIRs for the docking calculation of the complex structure.

In the case of apo-CaM, where $\Delta\delta_{ave}$ was 0.009 ppm, a $\Delta\delta_{cut-off}$ of 0.02 ppm is a reasonable criterion for the discrimination of interacting residues. This cut-off value was surpassed by residues Ser17, Lys21, Thr29, Thr34, Asn53, Ala57, Asn60, Gly61, Thr62, Ile63 and Asp64. In addition, the residues experiencing dramatic changes in their dynamics, i.e. Asp22, Gly23, Asp24, Gly25, Thr26 and Ile27, were also considered for selection as possible AIRs. As a consequence, the residues Asp22, Gly23, Asp24, Thr26, Thr29, Asn60, Gly61 and Thr62 were selected as active AIRs. Residues Ile27 and Ile63, on the other hand, were neglected as AIRs due to their low surface accessibility. The residues Ser17, Thr34, Asn53 and Ala57 were rejected as direct contact partners because of their peripheral location relative to the rest. For the same

reason, Lys21, Gly25 and Asp64 were selected only as passive AIRs. In addition, surface-accessible spatial neighbors of the active AIR residues (i.e. residues Thr28, Lys30, Glu31, Asp58 and Gly59) were introduced as passive AIRs (Table 7).

Table 7. Description of the FKBP38³⁵⁻¹⁵³ and apo-CaM residues that were used as active and passive AIRs in the docking calculations. $\Delta\delta$: combined chemical shift changes in ppm. SA: surface accessibility. L.N.: Line narrowing observed in apo-CaM upon complex formation with FKBP38³⁵⁻¹⁵³. In the case of FKBP38³⁵⁻¹⁵³, the surface accessibilities are reported as average values \pm RMSD from all 20 conformers of the NMR structure ensemble.

The 20 best structures of the FKBP38³⁵⁻¹⁵³/apo-CaM complex calculated with HADDOCK (Figure 40A) display a quite good structural convergence. However, a main cluster comprising 12 structures, including the energetically most favored structures as well as those with the higher buried surface area could be identified. The averages of the total intermolecular energy (E_{tot}) and buried surface area (BSA) for this cluster are -219.8 ± 59.7 kcal/mol and $1046 \pm 131 \text{ \AA}^2$, respectively, compared to values of -196.2 ± 65.6 kcal/mol and $998 \pm 151 \text{ \AA}^2$ for all 20 structures. After elimination of three more conformers from this cluster, i.e. those displaying higher intermolecular energies and lower buried surface areas, a cluster of 9 structures with even better quality remains (Figure 40B), as revealed by averages of -241.2 ± 50.5 kcal/mol for E_{tot} and $1095 \pm 112 \text{ \AA}^2$ for BSA. The structural statistics for this cluster, which can be considered as the final structure of the FKBP38³⁵⁻¹⁵³/apo-CaM complex, are shown in Table 8. Moreover, the potential energy associated with the AIRs makes an insignificant contribution to the total intermolecular energy in all selected structures, an indication that these are in good agreement with the experimental data.

The FKBP38³⁵⁻¹⁵³/apo-CaM complex seems to be favored by good surface complementarities between the proteins. Thus, the β C- β D loop of FKBP38³⁵⁻¹⁵³ (in particular the residues Asn76

and Gly77) is inserted into a cavity located between the central loops (AB and CD) of both EF-hand motifs in the N-terminal apo-CaM domain (Figure 41A). As a consequence, several hydrophobic contacts as well as hydrogen bonds are present between residues belonging to the β C- β D loop of FKBP38³⁵⁻¹⁵³ and residues in the CaM segments Asp22-Thr28 and Gly61-Thr62. In a similar manner, part of the AB loop belonging to apo-CaM, especially the segment Asp22-Asp24, is surrounded by the β C- β D loop and the outer part of the β -sheet of FKBP38³⁵⁻¹⁵³ (Figure 41B). Additional stabilization of the complex is provided by salt-bridge formation from Lys21 and Glu31 (both CaM) to Glu140 and Arg79 (both FKBP38³⁵⁻¹⁵³), respectively (Figure 41C); either one or both of these salt-bridges are present in most of the conformers.

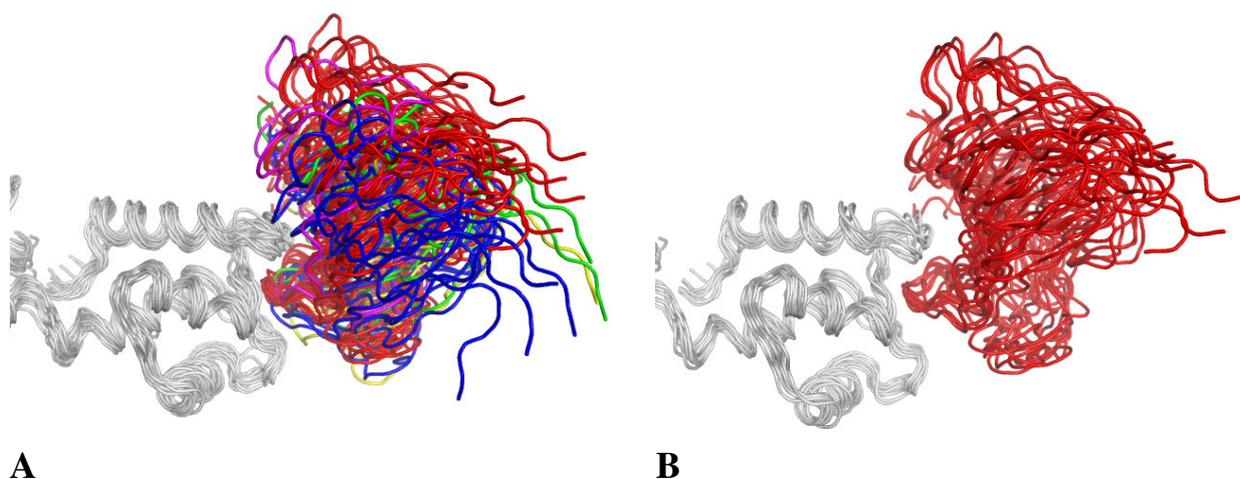

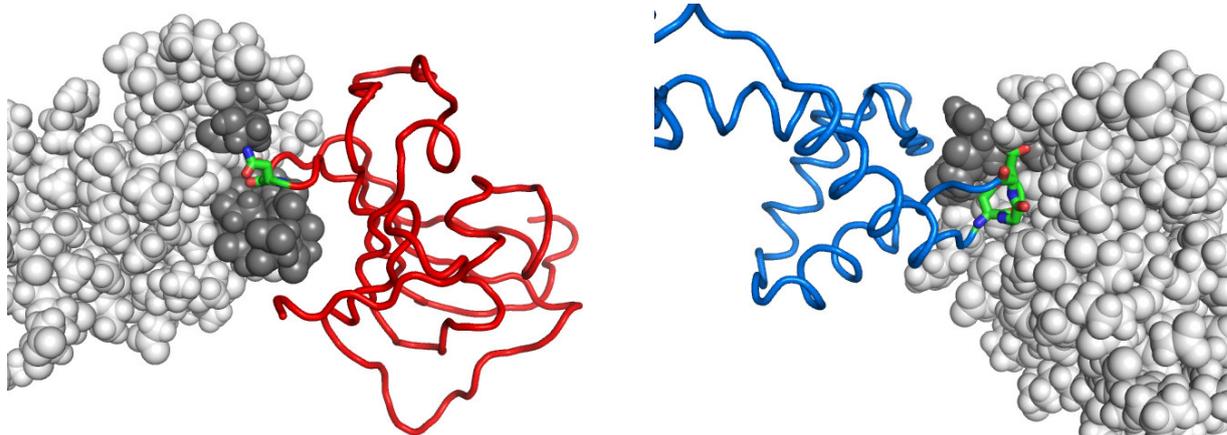

Figure 40. Ribbon representation of the backbone of the FKBP38³⁵⁻¹⁵³/apo-CaM complex (**A**) All 20 structures of the FKBP38³⁵⁻¹⁵³/apo-CaM complex are shown. The N-terminal apo-CaM domains (gray) are superposed, while the FKBP38³⁵⁻¹⁵³ molecules are presented in different colors, depending on their structural similarities. The main cluster is colored in red. (**B**) The 9 conformers considered as the final structure of the FKBP38³⁵⁻¹⁵³/apo-CaM complex are represented in the same manner as in (A).

Table 8. Statistics of the final 9 conformers of the FKBP38³⁵⁻¹⁵³/apo-CaM complex, sorted according to their total intermolecular energy. The backbone RMSDs were calculated for the segment FKBP38³⁶⁻¹⁵⁰ after superposition of CaM⁵⁻⁷⁵.

Figure 41. Structure of the apo-CaM/FKBP38³⁵⁻¹⁵³ complex. (A) The residues Asn76 and Gly77 from the β C- β D loop of FKBP38³⁵⁻¹⁵³ (stick model) are bound to a cavity at the surface of apo-CaM (CPK model), which is formed by segments Asp22-Thr28 and Gly61-Thr62 (dark gray). (B) The segment Asp22-Asp24 from the AB loop of apo-CaM (stick model) is surrounded by FKBP38³⁵⁻¹⁵³ (CPK model). The β C- β D loop from FKBP38³⁵⁻¹⁵³ is highlighted in dark gray. (C) Ribbon representation of the interface between apo-CaM (blue) and FKBP38³⁵⁻¹⁵³ (red). The side-chains of residues Lys21 and Glu31 (both CaM) and Glu140 and Arg79 (both FKBP38³⁵⁻¹⁵³) represented as stick model, form two salt-bridges (3.17 Å and 3.30 Å, respectively) in this conformer.

3.4.5.2. Three-dimensional structure of the FKBP38³⁵⁻¹⁵³/holo-CaM complex

For the calculation of the FKBP38³⁵⁻¹⁵³/holo-CaM complex, no experimental data regarding the interaction surface in FKBP38³⁵⁻¹⁵³ could be obtained due to denaturation of FKBP38³⁵⁻¹⁵³ in the experiment (see section 2.2.4.2.3.). Nevertheless, as the activation of FKBP38³⁵⁻¹⁵³ by CaM has been reported to occur in a Ca²⁺-independent manner (Edlich et al., in preparation), it could be assumed that the same FKBP38³⁵⁻¹⁵³ region interacts with apo- and holo-CaM. Therefore, the same FKBP38³⁵⁻¹⁵³ residues as in section 3.4.5.1. were selected for the HADDOCK calculation of the FKBP38³⁵⁻¹⁵³/holo-CaM complex (Table 9).

In the case of holo-CaM, were $\Delta\delta_{ave}$ was equal to 0.031 ppm, the $\Delta\delta_{cut-off}$ was set to 0.04 ppm. The residues showing either CSP above this cut-off or dynamic effects include the segments Phe12-Phe19, Asp24, Thr26-Ile27, Thr29-Glu31, Gly33-Thr34, Met36-Arg37, Leu48, Asp50, Ile52-Asp58, Asn60, Thr62-Asp64 and Glu67-Lys75. Residues located in the four helices of the N-terminal CaM domain were excluded as their CSPs probably represent secondary effects of the interaction. Moreover, residue Asp58 was chosen only as passive AIR due to its peripheral

location at the interaction surface. Hence, the residues Asp24, Thr26, Lys30, Asn60, Thr62 and Asp64 were selected as active AIRs, while their surface-accessible spatial neighbors, i.e. Asp22, Gly23, Gly25, Thr28, Gly59, Gly61, Phe65 and Pro66 were selected as passive AIRs in addition to Asp58 (Table 9).

Table 9. Description of the FKBP38³⁵⁻¹⁵³ and holo-CaM residues that were used as active and passive AIRs in the docking calculations. $\Delta\delta$: combined chemical shift changes in ppm. SA: surface accessibility. In the case of FKBP38³⁵⁻¹⁵³, the surface accessibilities are reported as average values \pm RMSD from all 20 conformers of the NMR structure ensemble.

Most of the 20 best structures of the FKBP38³⁵⁻¹⁵³/holo-CaM complex (Figure 42) calculated with HADDOCK can be grouped into two structural clusters, which consist of 9 (cluster I, Table 10) and 8 structures (cluster II, Table 11), respectively, and differ only by a rather small shift of the FKBP38³⁵⁻¹⁵³ molecule over the holo-CaM surface. The remaining three structures display a completely different orientation that can be discarded, however, as it does not explain observed contacts between the unstructured FKBP38 N-terminus (FKBP38¹⁻³⁴) and the CaM helix A (Katja Heydenreich, unpublished results). Although the structures belonging to cluster I exhibit a slightly better convergence, as revealed by the average backbone RMSD of 5.42 ± 2.03 Å compared to 5.84 ± 1.48 Å in cluster II, the latter can be considered the better solution for this complex structure, as it exhibits a slightly lower average intermolecular energy of -187.3 ± 43.1 kcal/mol (compared to -174.1 ± 39.5 kcal/mol in cluster I) and a considerably higher average BSA of 1182 ± 103 Å² (compared to 1042 ± 75 Å² in cluster I).

In the FKBP38³⁵⁻¹⁵³/holo-CaM complex structure, the loops AB (i.e. segment Asp22-Lys30) and CD (i.e. segment Asp58-Pro66) of holo-CaM are interacting with the β C- β D loop (i.e. segment Glu75-Arg79) and part of the β -sheet (external side) of FKBP38³⁵⁻¹⁵³, including for example, residues Trp36, Lys48, Leu50 (Figure 43). This complex is stabilized by several electrostatic

interactions, such as (i) a salt-bridge between Asp64 from holo-CaM and Lys48 from FKBP38 (present in 4 out of 8 structures) and (ii) some hydrogen bonds as for example between the side-chains of Asn60 (holo-CaM) and Glu75 (FKBP38³⁵⁻¹⁵³) (present in 7 structures) and between Thr62 H^{γ1} (holo-CaM) and the Glu75 backbone carbonyl oxygen (FKBP38³⁵⁻¹⁵³) (present in 5 structures) Most of these interactions are present in the lowest energy structure (Figure 44).

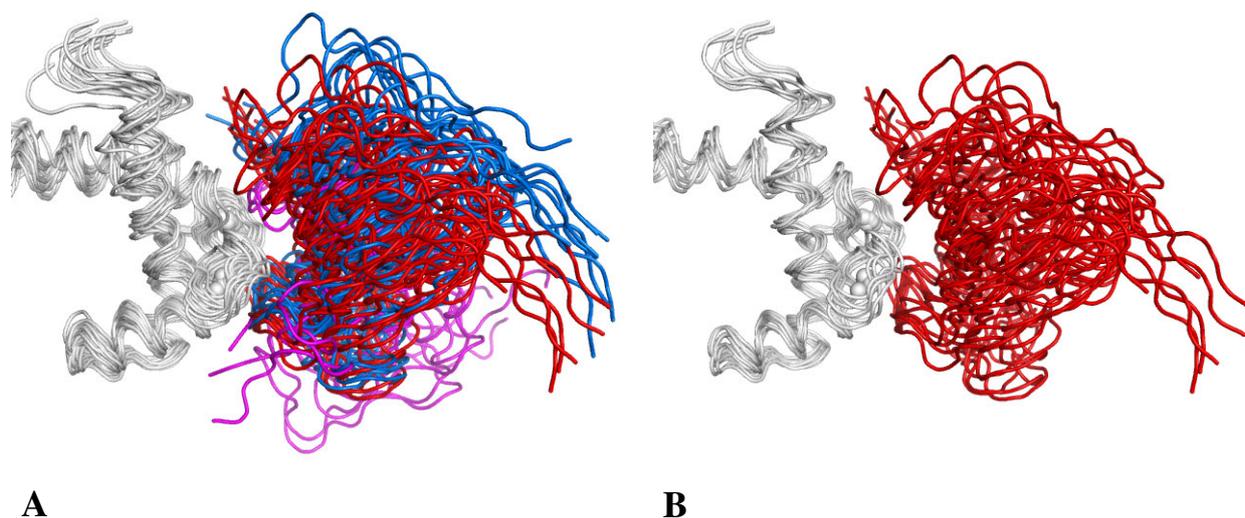

Figure 42. Ribbon representation of the backbone of the FKBP38³⁵⁻¹⁵³/holo-CaM complex. (A) All 20 structures of the FKBP38³⁵⁻¹⁵³/holo-CaM complex are shown. The N-terminal holo-CaM domains (gray) are superposed, while the FKBP38³⁵⁻¹⁵³ molecules belonging to the clusters I and II as well as the three structures displaying a different orientation are shown in blue, red and magenta, respectively. (B) The structures from cluster II, considered as the best solution for the FKBP38³⁵⁻¹⁵³/holo-CaM complex, are represented in the same manner as in (A).

Table 10. Statistics of the 9 conformers belonging to cluster I of the FKBP38³⁵⁻¹⁵³/holo-CaM complex, sorted according to their total intermolecular energies. The backbone RMSDs were calculated for the segment FKBP38³⁶⁻¹⁵⁰ after superposition of CaM⁵⁻⁷⁵.

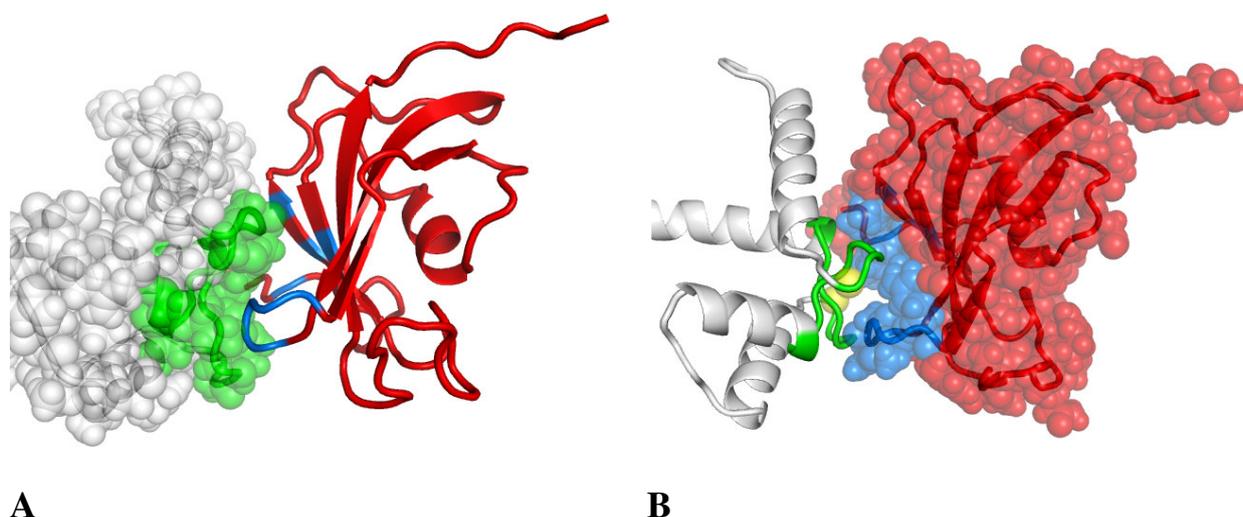

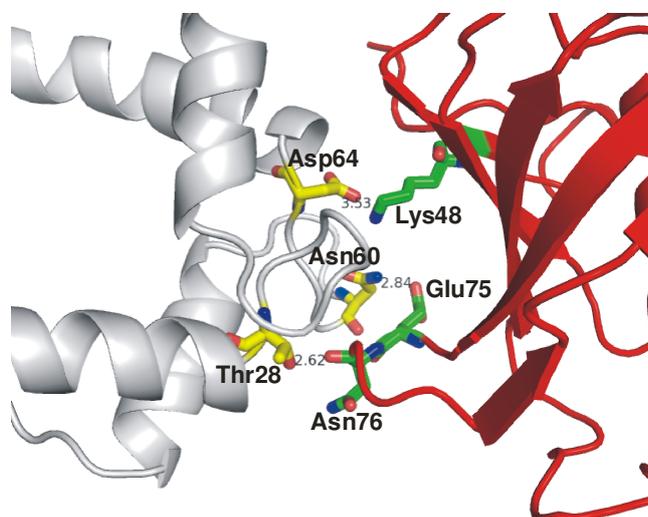

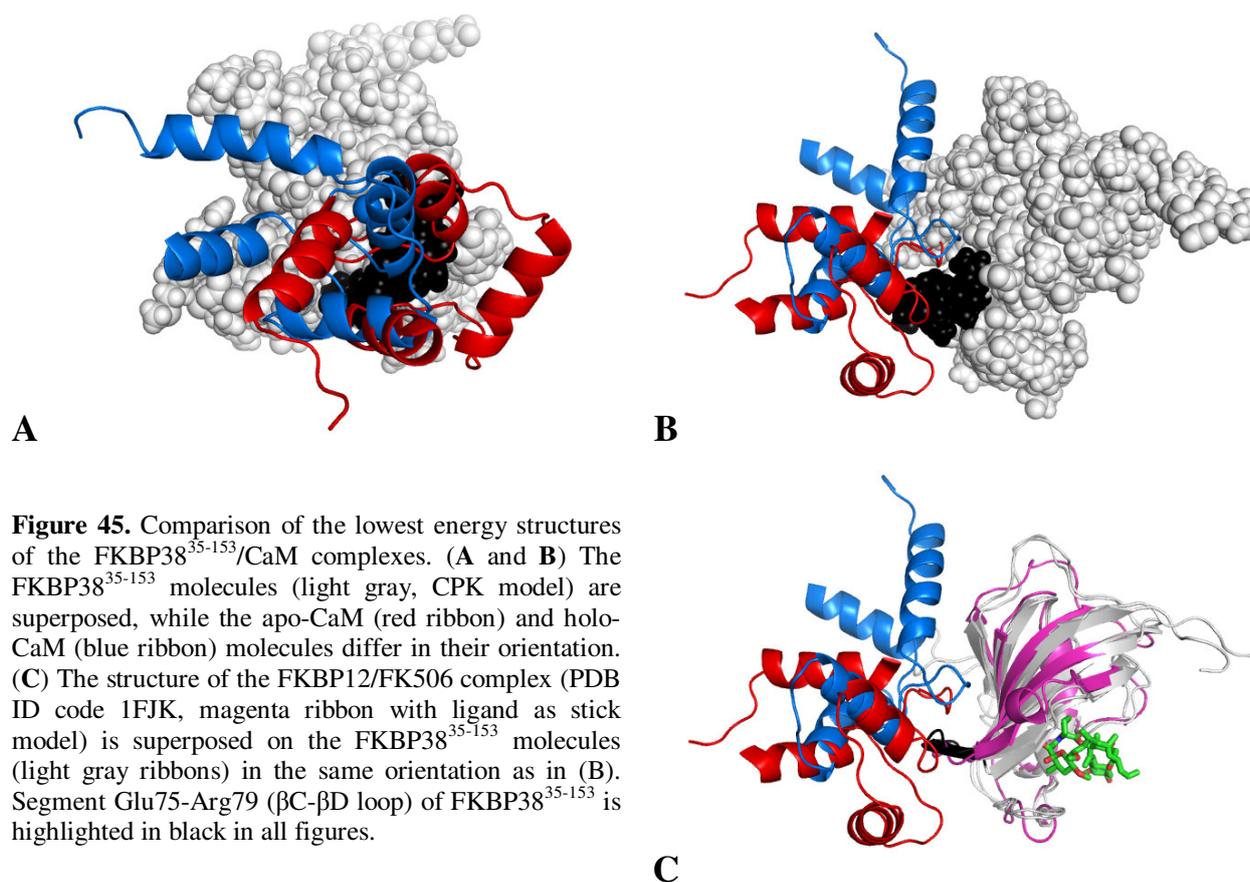

Figure 43. Structure of the FKBP38³⁵⁻¹⁵³/holo-CaM complex. **(A)** The holo-CaM molecule is shown as CPK model and the FKBP38³⁵⁻¹⁵³ backbone as ribbon. **(B)** The backbone of holo-CaM is represented as ribbon and FKBP38³⁵⁻¹⁵³ as CPK model. The segments Lys21-Lys30 and Asp58-Pro66 of holo-CaM as well as segment Glu75-Arg79 and residues Trp36, Lys48 and Leu50 belonging to FKBP38³⁵⁻¹⁵³, which mediate the interaction in the complex, are highlighted in green and blue, respectively. Calcium ions are shown as yellow spheres.

Figure 44. Electrostatic and polar interactions stabilizing the structure of the FKBP38³⁵⁻¹⁵³/holo-CaM complex. The interface between holo-CaM (gray ribbon) and FKBP38³⁵⁻¹⁵³ (red ribbon) in the lowest energy conformer of cluster II is displayed. Residues Thr28, Asn60 and Asp64 (all holo-CaM), as well as Asn76, Glu75 and Lys48 (all FKBP38³⁵⁻¹⁵³), involved in intermolecular hydrogen-bond and salt-bridge formation, are shown as sticks colored by atom type.

3.4.5.3. Comparison of the three-dimensional structures of the FKBP38³⁵⁻¹⁵³/CaM complexes

The lowest energy structures of the FKBP38³⁵⁻¹⁵³ complexes with apo- and holo-CaM are compared in Figure 45. Both complex structures diverge, as indicated by (i) a difference of $\sim 120^\circ$ in the orientation of the apo- and holo-CaM molecules relative to FKBP38³⁵⁻¹⁵³ and (ii) a considerable displacement of the CaM molecule over the FKBP38³⁵⁻¹⁵³ surface (Figure 45A and B). Thus, apo-CaM interacts with a surface centered at the β C- β D loop of FKBP38³⁵⁻¹⁵³, also contacting the external side of the β -sheet and the β E- β F loop, whereas the contact with holo-CaM is centered at the external side of the β -sheet of FKBP38³⁵⁻¹⁵³.

The origin of these structural differences is the diverging contact surfaces of apo- and holo-CaM (Figure 46). In the case of apo-CaM, the surface interacting with FKBP38³⁵⁻¹⁵³ features a cavity which accommodates the β C- β D loop of FKBP38³⁵⁻¹⁵³. Such a cavity is not present in holo-CaM, which may therefore prefer to bind to the flatter surface presented by the external side of the β -sheet of FKBP38³⁵⁻¹⁵³.

Although both complexes display different structural arrangements, they present a fundamental

characteristic in common: the interaction of CaM with the β C- β D loop of FKBP38³⁵⁻¹⁵³. This interaction might propagate through the N-terminal end of the β D strand, which in fact includes several resonances (i.e. the segment Val80-Glu82) that display broadened signals in the ¹H/¹⁵N-HSQC spectrum of FKBP38³⁵⁻¹⁵³ presumably due to increased backbone dynamics or conformational exchange. This could finally lead to a change in the orientation of the Glu83 side-chain, located in β D, which is considered to possibly be responsible for the inactivity of FKBP38³⁵⁻¹⁵³, as it is oriented towards the putative binding site where it would collide with the bound substrate (see section 3.2.). Moreover, the interaction of CaM with the β C- β D loop could also produce a conformational rearrangement at the long β E- β F loop, as both loops are in direct contact in the FKBP38³⁵⁻¹⁵³ structure. Such a rearrangement could also lead to the activation of FKBP38³⁵⁻¹⁵³, as the β E- β F loop is supposedly blocking the access to the active site of FKBP38. This activation of FKBP38³⁵⁻¹⁵³ by both apo- and holo-CaM had already been demonstrated in binding assays with Bcl-2 (Edlich et al., in preparation), which corroborates the relevance of both complex structures.

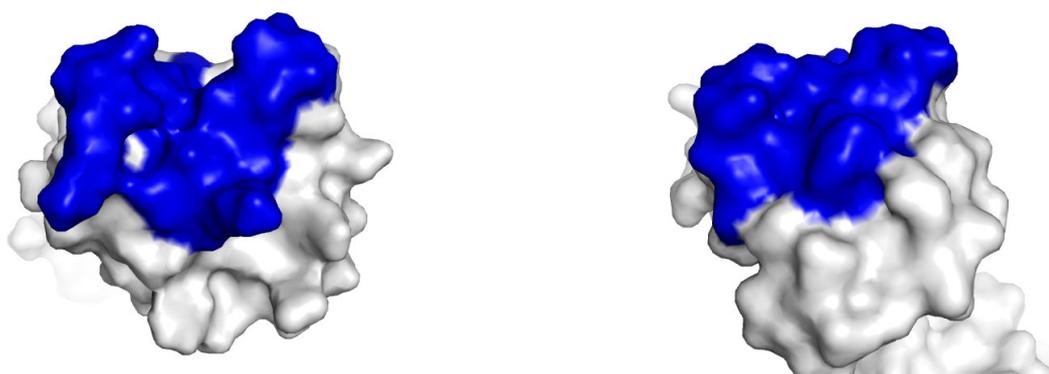

Figure 46. Comparison of the surfaces of apo-CaM (**left**) and holo-CaM (**right**), involved in the complex formation with FKBP38³⁵⁻¹⁵³. The residues interacting with FKBP38³⁵⁻¹⁵³ are highlighted in blue.

Another common feature of both complexes is the contact between the Trp36 indole ring of FKBP38³⁵⁻¹⁵³ and the N-terminal CaM domain. This explains the very similar fluorescence results obtained in titrations of FKBP38³⁵⁻¹⁵³ with apo- and holo-CaM (Edlich et al., in preparation).

3.5. Interactions of FKBP38²⁹⁰⁻³¹³ with holo-calmodulin

As already described in section 1.1.2., FKBP38 contains a putative CaM-binding site located at the C-terminal end of its TPR domain. This binding site was predicted by the Calmodulin Target Database (Yap et al., 2000; <http://calcium.uhnres.utoronto.ca/ctdb>) for the sequence Leu289-Gly312, with the highest probability in the segment Val293-Arg308. A peptide scan with a

synthetic peptide library of FKBP38 showed a Ca^{2+} -dependent binding to CaM by a peptide comprising residues Ala298-Leu311. This result was subsequently confirmed by binding and competition assays, which were carried out with a synthetic peptide corresponding to FKBP38²⁹⁰⁻³¹³ (Edlich et al., in preparation). In order to structurally characterize this interaction, a CSP study was performed (Figure 47).

The complex formation of ¹⁵N-labelled holo-CaM with FKBP38²⁹⁰⁻³¹³ produced an average combined chemical shift change $\Delta\delta$ of 0.017 ppm (Figure 48). The most pronounced effects were found in the C-terminal domain of the protein, with a maximal chemical shift perturbation of 0.100 ppm.

Figure 47. Section from the ¹H/¹⁵N-HSQC spectrum of ¹⁵N-labelled holo-CaM, showing the changes produced in the backbone resonances by the complex formation with FKBP38²⁹⁰⁻³¹³. The blue signals correspond to the free form of holo-CaM, while the red signals correspond to the FKBP38²⁹⁰⁻³¹³/holo-CaM complex.

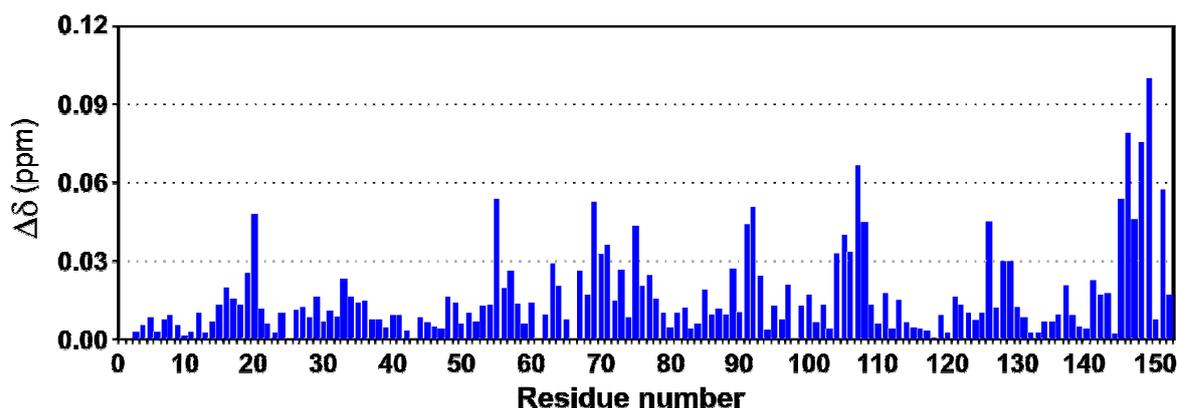

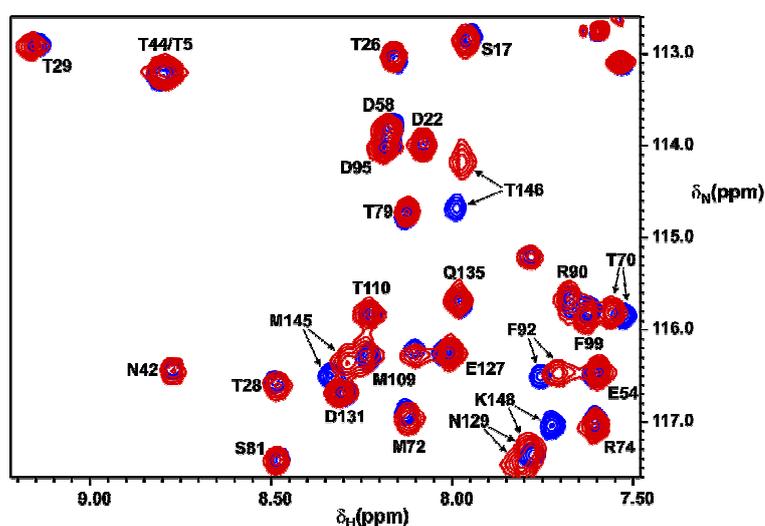

Figure 48. Overview of the combined chemical shift changes ($\Delta\delta$) observed in ¹⁵N-labelled holo-CaM upon addition of a 3-fold molar excess of FKBP38²⁹⁰⁻³¹³.

The CaM residues affected by the interaction with FKBP38²⁹⁰⁻³¹³ are located in different parts of the C-terminal domain (e.g. Val91-Phe92, Glu104-Val108, R126, Ala128-N129 and M145-K148), but most of them are located in or near its methionine-rich cleft (Figure 49), which

suggests that FKBP38²⁹⁰⁻³¹³ binds to this hydrophobic cavity in the C-terminal holo-CaM domain. This interaction could thus resemble that of the CaM complex with the C20W peptide of the plasma membrane Ca²⁺ pump (Elshort et al., 1999), where the C20W peptide binds to the hydrophobic cleft in the C-terminal CaM domain as shown in Figure 49C.

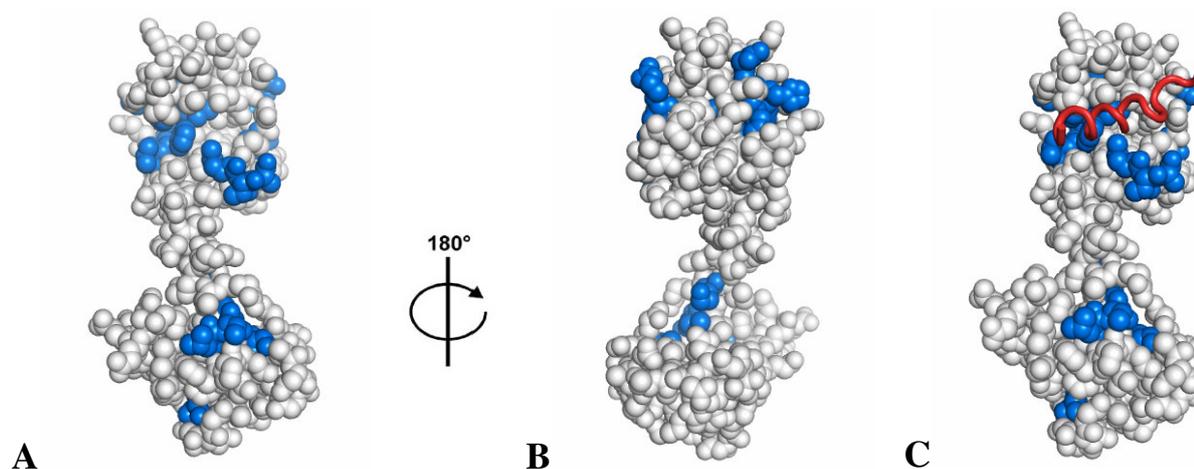

Figure 49. (A and B) Atomic model of holo-CaM showing the residues affected by the interaction with FKBP38²⁹⁰⁻³¹³. Residues featuring combined chemical shift changes higher than 0.03 ppm upon addition of FKBP38²⁹⁰⁻³¹³ are highlighted in blue. (C) The CaM/C20W complex is superposed to holo-CaM (i.e. to its C-terminal domain) and the C20W ligand presented as red ribbon.

At the same time, however, some resonances in the N-terminal holo-CaM domain, i.e. Asp20, Val55, Leu69-Met71 and Lys75, also experienced significant chemical shift changes upon complex formation with FKBP38²⁹⁰⁻³¹³ (Figures 48 and 49). With the exception of Asp20, all these residues are spatially close in the structure of holo-CaM, at a position near the protein surface and not related to the hydrophobic cleft of this domain. An experiment where ¹⁵N-labelled holo-CaM was titrated with only 0.8 equivalents of FKBP38²⁹⁰⁻³¹³ showed that these chemical shift changes in the N-terminal CaM domain arose in the same proportion as those observed in the C-terminal domain, which is a clear indication that they are not due to an excess of FKBP38²⁹⁰⁻³¹³. Rather, it suggests a collateral interaction of this part of the N-terminal domain with the FKBP38²⁹⁰⁻³¹³ ligand that is bound to the hydrophobic cleft in the C-terminal CaM domain. Therefore, it can be concluded that FKBP38²⁹⁰⁻³¹³ (i) interacts mainly with the hydrophobic cleft of the C-terminal holo-CaM domain and (ii) produces a secondary interaction with the N-terminal CaM domain.

For the titration with non-labelled holo-CaM, a partially ¹⁵N-labelled FKBP38²⁹⁰⁻³¹³ peptide was used. As a first step, the ¹H and ¹⁵N resonances of this molecule were assigned (Table 12) according to the classical assignment strategy (Wüthrich, 1986).

Table 12. ^1H and ^{15}N resonance assignments (in ppm) of FKBP38²⁹⁰⁻³¹³ at 278 K and pH 6.8. The chemical shift values of ^{15}N -labelled amide groups are highlighted in bold.

The results of the titrations of this partially ^{15}N -labelled peptide with (i) holo-CaM and (ii) the C-terminal domain of holo-CaM (holo-CaM⁷⁶⁻¹⁴⁸) are presented in Figure 50. In both titrations, the Leu311 amide signal experienced considerable chemical shift changes of more than 0.10 ppm for the H^N resonance and of ~ 2 ppm for the N resonance upon complex formation. Moreover, this signal broadened dramatically in the complexed forms. The remaining resonances present in the $^1\text{H}/^{15}\text{N}$ -HSQC spectrum were also affected by the complex formation with either holo-CaM or holo-CaM⁷⁶⁻¹⁴⁸, but to a much lower extent. This result suggests that Leu311 is directly involved in the interaction with holo-CaM, while the rest of the labelled residues, i.e. Leu292, Ala297, Ala305 and Gln299, are probably not in close contact with the protein. Furthermore, the fact that very similar effects were observed in both titrations indicates that the C-terminal domain is the one mainly responsible for the interaction with the CaM-binding site of FKBP38.

The observation that FKBP38²⁹⁰⁻³¹³ interacts with the C-terminal domain of holo-CaM is in good agreement with other results (Edlich et al., in preparation), which show that (i) holo-CaM⁷⁶⁻¹⁴⁸

interferes with the activation of FKBP38 by holo-CaM and (ii) FKBP38²⁹⁰⁻³¹³ forms a 1:1 complex with holo-CaM⁷⁶⁻¹⁴⁸ that reveals a binding constant comparable to the FKBP38/holo-CaM complex. This preference of FKBP38²⁹⁰⁻³¹³ for the C-terminal CaM domain is not an isolated case. Another CaM-target peptide structure has been reported where the target peptide binds only to the C-terminal CaM domain (Elshort et al., 1999).

Figure 50. Section from the ¹H/¹⁵N-HSQC spectrum of partially ¹⁵N-labelled FKBP38²⁹⁰⁻³¹³, showing the changes caused in the backbone resonances by the complex formation with holo-CaM and holo-CaM⁷⁶⁻¹⁴⁸. The black signals correspond to the free form of FKBP38²⁹⁰⁻³¹³, the red signals to the FKBP38²⁹⁰⁻³¹⁴/holo-CaM complex and the blue signals to the FKBP38²⁹⁰⁻³¹⁴/holo-CaM⁷⁶⁻¹⁴⁸ complex. The boxes represent the approximate positions of the very broad signal of Leu311 in the complexed forms, which are below the plot level.

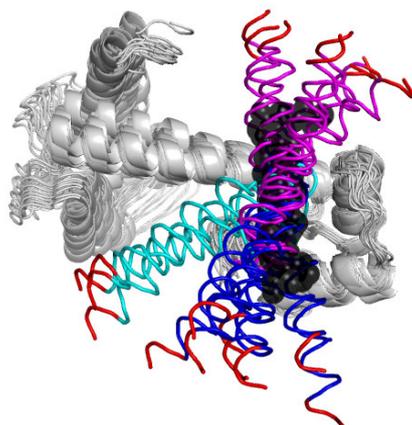

3.5.1. Three-dimensional structure of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex

For the docking calculation of the three-dimensional structure of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, the selection of the AIRs in holo-CaM was carried out in a different manner. This is due to the fact that FKBP38²⁹⁰⁻³¹³ binds to the inner cavity of the C-terminal domain holo-CaM. Therefore, only residues located in this inner cavity were selected as AIRs, instead of surface accessible residues. A cut-off of 0.03 ppm was chosen for the combined chemical shift changes $\Delta\delta$, which is considerably larger than the average value of 0.017 ppm. The residues that exceed this cut-off and either belong to the N-terminal holo-CaM domain, i.e. Asp20, Val55, Leu69-Met71 and Lys75, or are located at the outer surface of the C-terminal holo-CaM domain, i.e. Glu104, Arg106, His107, Arg126 and Asn129, were not considered for the calculation. Lys148, the C-terminal residue of CaM, was also rejected as constraint. The rest of the residues surpassing the $\Delta\delta_{\text{cut-off}}$, i.e. Val91, Phe92, Leu105, Val108, Ala128, Met145, Thr146 and Ala147, which are located in the inner cavity of the C-terminal CaM domain, were selected as active AIRs. Other residues defining this inner cavity, i.e. Ile85, Glu87, Ala88, Met109, Leu112, Met124, Ile125, Glu127 and Met144, were subsequently selected as passive AIRs.

In the case of FKBP38²⁹⁰⁻³¹³, the only residue selected as active AIR was Leu311, which displays dramatic changes both in the chemical shift values and in the signal line-width upon complex formation with holo-CaM or holo-CaM⁷⁶⁻¹⁴⁸. In addition, all residues in the segment FKBP38²⁹⁸⁻³¹² were selected as passive AIRs, with the exception of the residues Gln299 and Ala305, which were ¹⁵N-labelled but displayed no significant effects upon complex formation. The segment FKBP38²⁹⁰⁻²⁹⁷ was excluded as possible contact region, since this part of the protein (based on the expected similarity of the FKBP38 TPR domain of with those of FKBP51 and FKBP52) should be integrated in the structure of the TPR domain and therefore inaccessible for complex formation with CaM. Two residues in this segment, i.e. Leu292 and Ala297, were ¹⁵N-labelled but not affected by the interaction with holo-CaM or holo-CaM⁷⁶⁻¹⁴⁸, which supports the assumption that this segment is not involved in the interaction with CaM. Moreover, considering that Leu111 should be located inside the hydrophobic cavity of the C-terminal CaM domain, it is unlikely that a segment longer than 14 residues can fit into the narrow, ~18 Å long binding cleft, even in a helical arrangement.

The 20 structures obtained from the docking calculation of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex can be grouped in three clusters (Figure 51A). Clusters I and cluster II, each consisting of 8 conformers, present the peptide in a similar orientation to that of other known CaM/peptide complexes, as for example the CaM/C20W complex (Elshort et al., 1999), whereas in cluster III, consisting of only 4 conformers, FKBP38²⁹⁰⁻³¹³ adopts a nearly perpendicular orientation (forming an angle of ~60° to the other two clusters). Moreover, the conformers from cluster III display significantly higher intermolecular energies, larger AIR violations (reflected by higher AIR energies) and lower BSA values compared to clusters I and II (Figure 51B), which is a strong indication that this smaller cluster does not represent a reasonable solution for the complex structure.

The remaining clusters I and II present much better structural statistics (Figure 51B), but differ from each other in the direction the FKBP38²⁹⁰⁻³¹³ molecule lies inside the hydrophobic cavity of the C-terminal CaM domain. While FKBP38²⁹⁰⁻³¹³ adopts in cluster II the opposite N-to-C direction as for example the C20W molecule in the CaM/C20W complex (Figure 51A), in cluster I it has the same direction as C20W, which is also observed in the vast majority hitherto reported CaM/peptide complex structures (Vetter and Leclerc, 2003; Ishida and Vogel, 2006). Unfortunately, no clear prediction can be made for one or the other direction based on the sequence of this FKBP38 segment, since (i) it shows no homology to other CaM-binding motifs and (ii) the balance of positively-charged amino acids at its N- and C-terminal ends is nearly equal.

A**B**

Cluster	No. conf.	E_{tot} (kcal/mol)	E_{AIRs} (kcal/mol)	BSA (\AA^2)
I	8	-231.1 ± 82.5	0.01 ± 0.02	1510 ± 236
II	8	-189.7 ± 74.9	0.17 ± 0.40	1427 ± 127
III	4	-145.0 ± 71.3	1.60 ± 1.13	1132 ± 109

Figure 51. Calculated structures of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex. **(A)** All 20 structures of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex are shown. The C-terminal holo-CaM domains (gray ribbon) are superposed, while the FKBP38²⁹⁰⁻³¹³ molecules are represented in blue (cluster I), magenta (cluster II) or cyan (cluster III). The N-terminal ends of the FKBP38²⁹⁰⁻³¹³ molecules are highlighted in red. The backbone of the C20W molecule taken from the structure of its complex with CaM (PDB ID code 1CFF) is represented as CPK model in black. **(B)** Statistics table comparing average energies and BSAs of the three clusters obtained for the FKBP38²⁹⁰⁻³¹³/holo-CaM complex.

The direction found in cluster I, however, can be considered as the one most likely for the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, as this cluster displays (i) the lowest average intermolecular energy, (ii) the highest average BSA, and (iii) the same direction as the majority of the known CaM/peptide complex structures. This cluster (Table 13) seems to be favored by better charge complementarities between the peptide and CaM, which stabilize the complex. Especially the lowest energy structure of this cluster, by far the one showing the lowest electrostatic, van der Waals and AIR energy values, and displaying a very similar backbone conformation as the CaM/C20W complex (Figure 52A), seems to be the best solution for the FKBP38²⁹⁰⁻³¹³/holo-CaM complex structure. In this structure, the side-chains of two hydrophobic residues, i.e. Tyr307 and Leu311, are anchoring the peptide inside the hydrophobic cavity of the C-terminal CaM domain, in addition to Glu303 (Figure 52A). Consequently, these side-chains belonging to FKBP38²⁹⁰⁻³¹³ interact with several hydrophobic residues in the CaM binding cavity. Moreover, the residues that were ¹⁵N-labelled but displayed no chemical shift perturbations upon complex formation, i.e. Leu292, Ala297, Gln299 and Ala305, all show no contacts with CaM (Figure 52B), which provides further support for the selection of this structure.

The presence of a glutamate side-chain inside the hydrophobic cleft of CaM certainly is energetically not favored, also with respect to the acidic character of CaM. This could be the reason for the relatively low affinity of FKBP38²⁹⁰⁻³¹³ for CaM, as indicated by a K_D of 1.5 μM (Edlich et al., in preparation), whereas other CaM/peptide complexes feature dissociation constants in the nM range.

Table 13. Statistics of the 8 conformers belonging to cluster I of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex, sorted according to their total intermolecular energy. The backbone RMSDs were calculated for the segment FKBP38²⁹⁸⁻³¹² after superposition of CaM⁸⁵⁻¹⁴⁵.

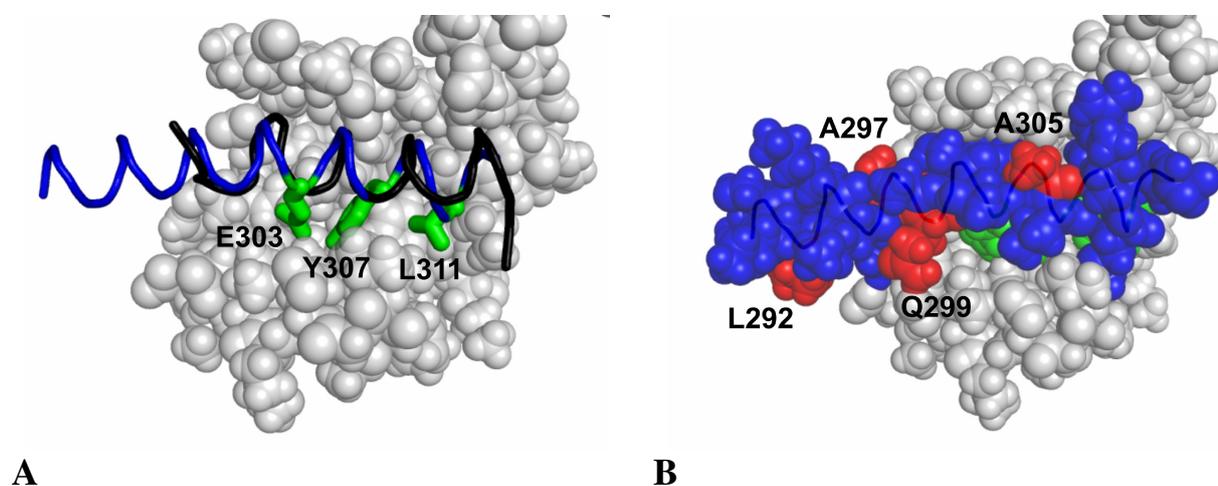

Figure 52. Structure of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex. (A) The backbone traces of FKBP38²⁹⁰⁻³¹³ (blue) and C20W (black, from the CaM/C20W complex structure, PDB ID code 1CFF) are represented as ribbons, while holo-CaM is shown as CPK model. The side-chains of Glu303, Tyr307 and Leu311 from FKBP38²⁹⁰⁻³¹³ are represented as green stick models. (B) CPK model of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex. CaM and FKBP38²⁹⁰⁻³¹³ are shown in light gray and blue, respectively. The residues Glu303, Tyr307 and Leu311, anchored to hydrophobic cavity of holo-CaM, are colored in green, while the residues Leu292, Ala297, Gln299 and Ala305, which show no direct contacts with holo-CaM, are highlighted in red.

3.6. Three-dimensional models of the overall FKBP38/CaM complexes

The three FKBP38/CaM complex structures determined in this work (i.e. FKBP38³⁵⁻¹⁵³/apo-CaM, FKBP38³⁵⁻¹⁵³/holo-CaM and FKBP38²⁹⁰⁻³¹³/holo-CaM) were finally combined to obtain models representing the FKBP38³⁵⁻³¹³/semiloading-CaM and FKBP38³⁵⁻³¹³/holo-CaM complexes, which are considered to be the active forms of FKBP38 (Edlich et al., unpublished results). These overall complexes (Figure 53) display slightly different quaternary structures, as a result of the diverging relative arrangements found between the FKBP38³⁵⁻¹⁵³/apo-CaM and FKBP38³⁵⁻¹⁵³/holo-CaM complexes. Both models, however, seem to present a reasonable structural quality,

as neither the different protein domains nor the linker regions show any significant deformations. Thus, the TPR domains of both complexes (i.e. the segment FKBP38¹⁵⁵⁻²⁸¹, which includes the three TPR motifs) display backbone conformations rather similar to that of FKBP51, as indicated by RMSDs of 1.75 and 2.03 Å for the FKBP38³⁵⁻³¹³/semiloading-CaM and FKBP38³⁵⁻³¹³/holo-CaM complexes, respectively. Furthermore, the connecting CaM linkers display similar lengths as in other CaM complexes, comprising the segment Met76-Ser81 in the FKBP38³⁵⁻³¹³/semiloading-CaM complex and Arg74-Ser81 in the FKBP38³⁵⁻³¹³/holo-CaM complex. These results therefore corroborate the feasibility of a complex that features two simultaneous binding interactions between FKBP38 and CaM.

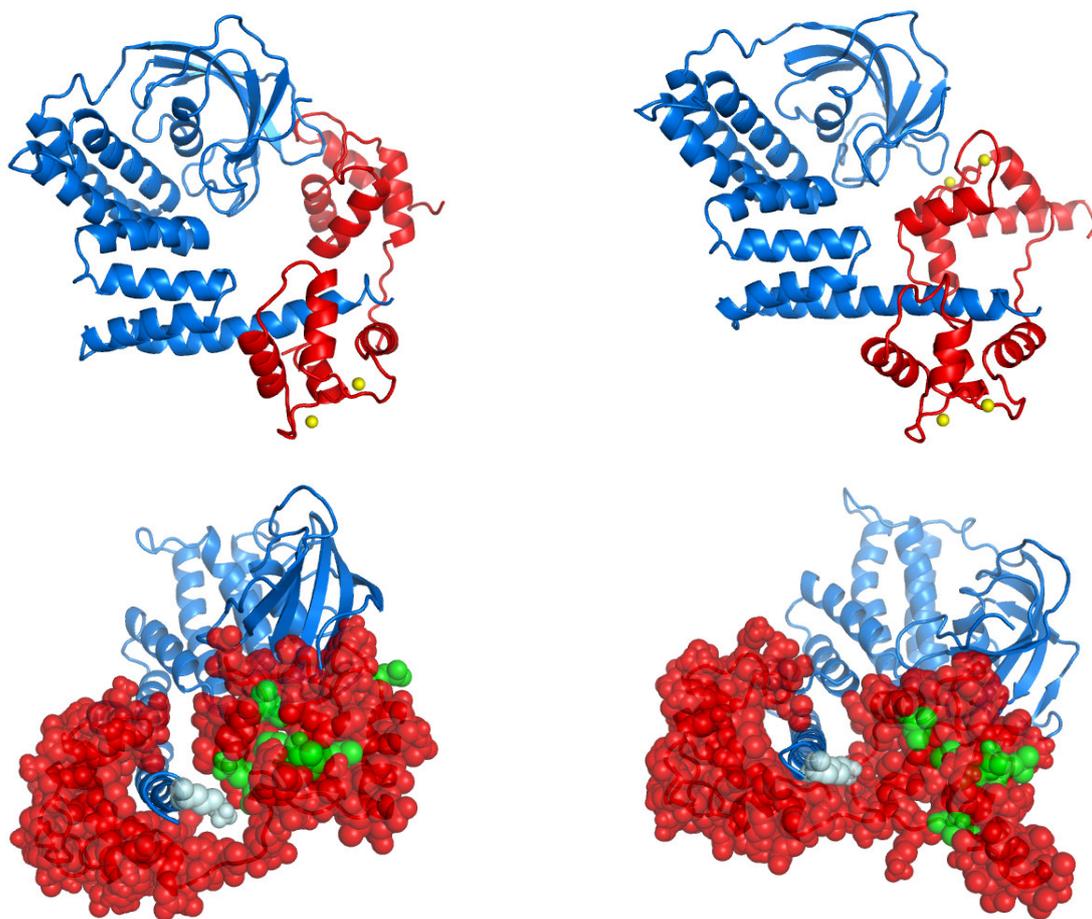

Figure 53. Structures of the FKBP38³⁵⁻³¹³/semiloading-CaM (**upper panel left**) and FKBP38³⁵⁻³¹³/holo-CaM (**upper panel right**) complexes. The backbone traces of FKBP38³⁵⁻³¹³ (blue) and CaM (red) are represented as ribbons and the Ca²⁺ atoms as yellow spheres. The TPR domains of FKBP38 are presented in the same orientation. In the **lower panel**, the CaM molecules are shown as CPK models, with the residues in the N-terminal CaM domain that displayed chemical shift changes upon binding to FKBP38²⁹⁰⁻³¹³ (i.e. Asp20, Leu69, Thr70, Met71 and Lys75) highlighted in green. Residue Lys309 of FKBP38, which extends towards the N-terminal CaM domain, is also shown as CPK model in light cyan.

In both structures, the CaM molecule is partially wrapped - to a higher or lower extent - around the CaM-binding site of FKBP38 (Figure 53, lower panel). As a consequence, the Lys309 side-chain of FKBP38, which is part of this CaM-binding site, is oriented in both structures towards

the N-terminal CaM domain. This may explain the chemical shift perturbations observed at the N-terminal CaM domain upon complex formation with FKBP38²⁹⁰⁻³¹³ (see section 3.5.).

Interestingly, both models show no additional interactions between the TPR domain of FKBP38 and the CaM molecule. Therefore, the overall FKBP38/CaM complex can be considered as a combination of two individual (i.e. C-terminal ↔ C-terminal and N-terminal ↔ N-terminal) binding modes, lacking any additional stabilizing interactions to those already observed in the individual binding modes. This result is in good agreement with (i) the relatively low binding affinity between both proteins and (ii) with the observation that the affinity of FKBP38²⁹⁰⁻³¹³ to CaM is comparable to that of the entire FKBP38 molecule, as revealed by competition assays and ITC experiments (Edlich et al., in preparation).

3.6.1. Comparison of the overall FKBP38³⁵⁻³¹³/CaM complexes with other known CaM complexes

The three-dimensional structures of the FKBP38³⁵⁻³¹³/CaM complexes display certain similarities to other known CaM/target protein structures. For example, the binding of FKBP38²⁹⁰⁻³¹³ to the CaM C-terminal domain resembles the CaM/C20W complex (Elshorot et al., 1999), which was already discussed in detail in section 3.5.1. The most remarkable similitude, however, can be found when FKBP38³⁵⁻³¹³/CaM is compared to the complex of CaM with the exotoxin edema factor from *Bacillus anthracis* (Drum et al., 2002).

In both CaM complexes (Figure 54), interactions occur between both CaM domains and different parts of the target proteins (either FKBP38 or edema factor). First, a helical part of the target protein (i.e. segment Arg300-Asn313 in FKBP38 and segment Asn521-Tyr536 in edema factor) binds to the hydrophobic cleft of the Ca²⁺-loaded C-terminal CaM domain. Furthermore, in the complex with edema factor the CaM molecule is tightly inserted between the CA domain and the helical domain of the edema factor, which results in several additional interactions of both CaM domains with the target protein, whereas in the FKBP38³⁵⁻³¹³/CaM complex the only additional interaction occurs between the N-terminal CaM domain (i.e. a surface region centered at the Ca²⁺-binding sites) and the catalytic domain of FKBP38. As a result, there is a significant difference in the binding affinities of CaM for edema factor ($K_D \sim 10^{-10}$ M) and FKBP38 ($K_D \sim 10^{-6}$ M).

Another difference between the two complexes is that the CaM molecule adopts different inter-

domain orientations in both structures. In the edema factor/CaM complex the CaM molecule is extended, whereas in the FKBP38³⁵⁻³¹³/CaM complex it is partially wrapped around the FKBP38³⁰⁰⁻³¹³ segment. Moreover, the N-terminal CaM domain is Ca²⁺-free in the edema factor complex, while it can be either Ca²⁺-free or Ca²⁺-bound in the complex with FKBP38.

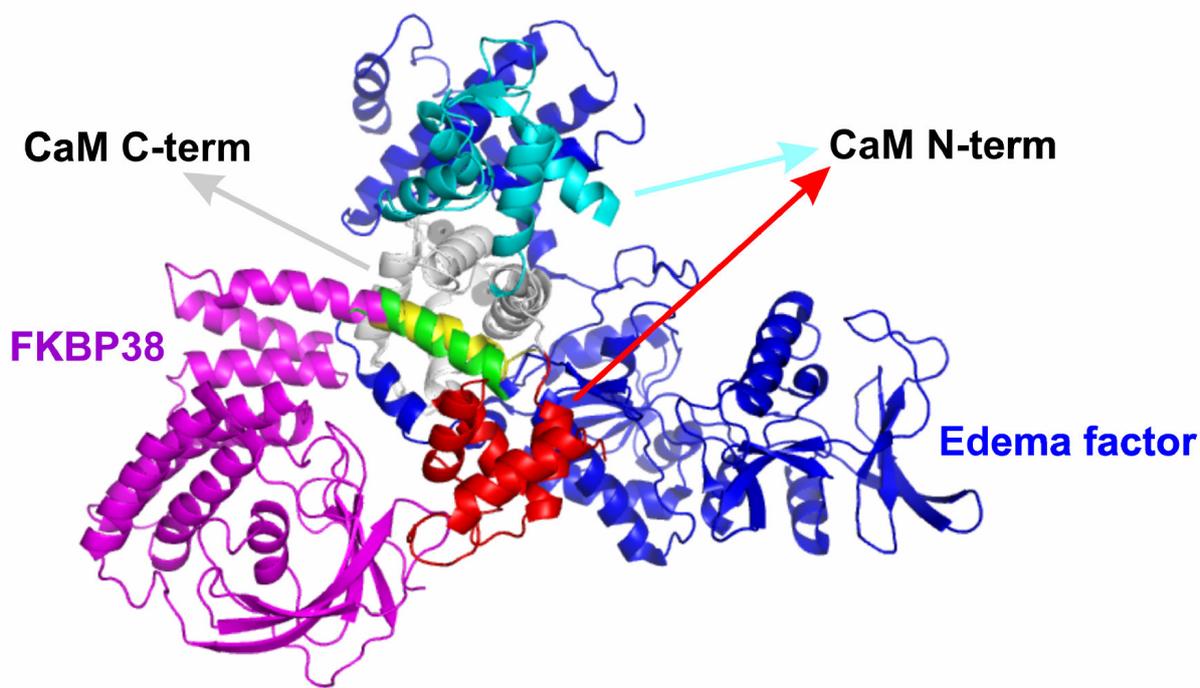

Figure 54. Comparison of the overall structures of the edema factor/CaM and FKBP38³⁵⁻³¹³/semiloaded-CaM complexes. The C-terminal CaM domains (grey) are superposed, while the N-terminal CaM domains are colored in red (edema factor/CaM) and cyan (FKBP38³⁵⁻³¹³/semiloaded-CaM). The helical target protein segments bound to the C-terminal CaM domain are highlighted in green (edema factor/CaM) and yellow (FKBP38³⁵⁻³¹³/semiloaded-CaM).

In both systems, the result of complex formation is an activation of the respective target protein. However, in the edema factor complex this activation is the result of a formation of an active site by protein regions that were solvent exposed in absence of CaM, in what has been referred to as an “active site remodeling” activation mechanism. In the FKBP38 complex, however, the activation seems to be the result of very subtle structural modifications which the N-terminal CaM domain introduces in the catalytic domain of FKBP38, influencing the β D strand and the β E- β F loop of this FKBP domain. Up to date, no structure has been published which displays similar interactions as those found between FKBP38 and CaM. Hence, the FKBP38/CaM system features a novel scenario of enzyme activation by CaM: the C-terminal CaM domain binds to a part of the target molecule (i.e. the CaM-binding site of FKBP38) with higher affinity, subsequently facilitating the lower affinity interaction of the N-terminal CaM domain with a second (in this case the catalytic) domain of the enzyme, thereby producing small conformational changes which lead to activation.

4. Summary

The human FKBP38 is a peptidyl prolyl *cis/trans* isomerase of the FKBP (FK506-binding protein) family, which has been found to play a key role in neuronal apoptosis. This constitutively inactive protein is the first PPIase that has been found to be regulated by calmodulin (CaM) and calcium (Ca²⁺), as only the FKBP38/CaM/Ca²⁺ complex displays FKBP activity and can inhibit the anti-apoptotic effector Bcl-2. The main aims of this work are the structural study of (i) the catalytic (FKBP) domain of FKBP38 and (ii) the interactions of FKBP38 with CaM/Ca²⁺, which lead to its activation. The following results have been obtained:

- A construct comprising the catalytic domain of human FKBP38, FKBP38³⁵⁻¹⁵³, was successfully cloned, expressed and purified for biochemical and structural studies. This construct displays a reasonable stability. It was expressed and purified in large amounts suitable for both the preparation of isotopically labelled NMR samples and crystallization.
- All ¹H and ¹⁵N resonances of FKBP38³⁵⁻¹⁵³ were assigned. The good signal dispersion of these resonances provided the basis for an NMR-based structure elucidation and for the study of its interactions with CaM and Ca²⁺.
- The three-dimensional structure of FKBP38³⁵⁻¹⁵³ was determined by high-resolution NMR spectroscopy. It displays the typical “half β-barrel” fold of FKBP domains. This structure explains the lack of FKBP activity of FKBP38³⁵⁻¹⁵³ due to specific differences between FKBP38³⁵⁻¹⁵³ and FKBP12. More precisely: (i) the lack of a loop that disrupts the βD strand is missing in FKBP38³⁵⁻¹⁵³ and (ii) the long βE-βF loop blocks the entry portal to the “active site” of FKBP38³⁵⁻¹⁵³. Considerable differences in the net charge around the active site between FKBP38³⁵⁻¹⁵³ and FKBP12 could also play a role in the substrate discrimination.
- The structure of FKBP38³⁵⁻¹⁵³ cannot mimic that of the FKBP12/FK506 complex. This supports the observation that FKBP38 cannot inhibit the protein phosphatase calcineurin in absence of bound FK506.
- For the first time, a weak binding of Ca²⁺ to an FKBP domain has been demonstrated in the case of FKBP38³⁵⁻¹⁵³. The binding of Ca²⁺ (and also Mg²⁺) to the βD-α loop of FKBP38³⁵⁻¹⁵³ has been characterized by NMR chemical shift perturbation mapping, ITC experiments and fluorescence spectroscopy. Structural insight into this binding event was provided by a crystal structure of FKBP38³⁵⁻¹⁵³, which has been determined at 1.05 Å resolution. The binding of Ca²⁺ to FKBP38³⁵⁻¹⁵³ might be related to a further regulation of the interaction(s) between FKBP38 and Bcl-2.
- The backbone ¹H and ¹⁵N amide resonances of apo- and holo-CaM were completely assigned

at the conditions used in the present study. These assignments allowed the investigation of the interactions of both CaM forms with FKBP38 by means of chemical shift perturbation mapping.

- Apo-CaM binds to a surface centered at the β C- β D loop of FKBP38³⁵⁻¹⁵³.
- FKBP38³⁵⁻¹⁵³ binds to the N-terminal domain of both apo- and holo-CaM. These interactions are centered at the AB and BC loops of CaM. No interactions were found with the C-terminal CaM domain. The backbone conformation of the CaM segments involved in the interaction with FKBP38³⁵⁻¹⁵³ is very similar in both CaM forms, which most likely is the reason for the Ca²⁺-independence of this interaction.
- The structures of FKBP38³⁵⁻¹⁵³ in complex with apo- and holo-CaM were elucidated by docking calculations using the information provided by the chemical shift perturbation experiments. These structures provide an explanation for the activation of FKBP38 upon CaM binding, since both CaM forms interact with the β C- β D loop. This may result in conformational changes either in the Glu83 side-chain or in the long β E- β F loop, which are both possible factors with respect to the inherent lack of activity of FKBP38³⁵⁻¹⁵³.
- A peptide comprising the CaM binding site of FKBP38, i.e. the segment FKBP38²⁹⁰⁻³¹³, was completely assigned for the study of its interactions with holo-CaM.
- FKBP38²⁹⁰⁻³¹³ binds to the hydrophobic cavity of the C-terminal holo-CaM domain.
- The structure of the FKBP38²⁹⁰⁻³¹³/holo-CaM complex was determined by means of docking calculations. This complex resembles the structure of holo-CaM in complex with the C20W peptide from the plasma membrane Ca²⁺ pump, where the peptide is bound only to the C-terminal CaM domain. The insertion of the Glu303 side-chain into the hydrophobic binding cavity of CaM may provide an explanation for the relatively low binding affinity of FKBP38.
- Overall model structures of the FKBP38³⁵⁻³¹³/holo-CaM and FKBP38³⁵⁻³¹³/semiloading-CaM complexes were simulated by means of molecular dynamics calculations. These structures seem to be reasonable approximations of the active FKBP38/CaM/Ca²⁺ complexes and are in good agreement with the biophysical data that is presently available.
- A comparison of the structures of the FKBP38³⁵⁻³¹³/CaM complexes with the edema factor/CaM complex reveals certain similarities. Differences in the enzyme activation exist, however, as the activation of FKBP38 originates from subtle structural modifications caused in its catalytic domain by the interaction with CaM. Hence, the activation of FKBP38 by CaM represents a novel scenario of enzyme activation by CaM.

The activation of FKBP38 by CaM can be summarized as the result of the formation of a 1:1 complex between both proteins, which features two binding modes: one between the CaM-

binding site of FKBP38 and the Ca^{2+} -bound C-terminal CaM domain, and another between the catalytic FKBP domain of FKBP38 and the N-terminal CaM domain that is Ca^{2+} independent. The latter interaction apparently causes certain conformational changes in the FKBP domain that lead to the activation of FKBP38 upon CaM/ Ca^{2+} binding. Further investigations will be needed to determine the structural basis of substrate binding to the activated FKBP38/CaM/ Ca^{2+} complex.

Table 13. Statistics of the 8 conformers from cluster I of the FKBP38 ²⁹⁰⁻³¹³ /holo-CaM complex	82

7. Abbreviations

AA	Amino acid
AIR	Ambiguous interaction restraint
Apo-CaM	Calcium-free calmodulin
Bcl-2	B-cell lymphoma protein 2
bp	Base pair
BSA	Buried surface area
CaM	Calmodulin
CaMKK	CaM-dependent kinase kinase
CaN	Calcineurin (protein phosphatase 2B, PP2B)
COSY	Correlated spectroscopy
CsA	Cyclosporin A
CSP	Chemical shift perturbation
Cyp	Cyclophilin
DEAE	Diethylaminoethyl
DM-CHX	N-(N',N'-dimethylcarboxamidomethyl)cycloheximide
DNA	Deoxyribonucleic acid
dNTP	Deoxyribonucleotide phosphate
EDTA	Ethylene-diamine-tetraacetic acid
EF-hand	Ca ²⁺ -binding motif
EGTA	Ethylenglycol-bis(β-aminoethylether)N,N,N',N'-tetraacetic acid
FKBP	FK506-binding protein (human if not otherwise indicated)
GPI1046	3-(3-pyridyl)-1-propyl(2S)-1-(3,3-dimethyl-1,2-dioxopentyl)-2-pyrrolidinecarboxylate
HEPES	N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid
holo-CaM	Calmodulin saturated with calcium
Hsp90	Heat shock protein 90
HSQC	Heteronuclear single quantum correlation
HTQC	Heteronuclear triple quantum correlation
IPTG	Isopropyl-β-D-thiogalactopyranoside
ITC	isothermal titration calorimetry
MALDI-TOF	Matrix-assisted laser desorption/ionization time-of-flight mass

	spectrometry
MD	Molecular dynamics
MES	2-(N-morpholino)ethanesulfonic acid
mTOR	mammalian target of rapamycin
NFAT	Nuclear factor of activated T-cell
NOE	Nuclear Overhauser enhancement
NOESY	Nuclear Overhauser enhancement spectroscopy
OD	Optical density, absorbance
OMIM	Online Mendelian inheritance in man
PCR	Polymerase chain reaction
PDB	Protein data bank
PEG	Polyethyleneglycol
PPIase	Prolyl <i>cis/trans</i> isomerase
ppm	Parts per million
PSI	Pounds per square inch
RMSD	Root mean square deviation
RNAi	RNA interference
rpm	Rotations per minute
SDS	Sodium dodecylsulfate
SDS-PAGE	Sodium dodecylsulfate - polyacrylamide gel electrophoresis
siRNA	Small interfering RNA
SK channel	small conductance Ca^{2+} -activated K^{+} channel
smMLCK	Smooth muscle myosin light chain kinase
TAE	TRIS-acetate-EDTA
TOCSY	Total correlated spectroscopy
TPPI	Time proportional phase incrementation
TPR	Tetratricopeptide repeat
TRIS	Tris-(hydroxymethyl)-aminomethane
U	Unit (for enzymes)
UV-VIS	Ultra violet – visible

8. Appendix

8.1. Acknowledgments

I want to express my gratitude to several persons who made a direct or indirect contribution to the fulfillment of this work.

First to my advisor P.D. Dr. Christian Lücke, for offering me this interesting research project, for his dedicate supervision and for all I learned from him.

To Prof. Dr. Gunter Fischer, who provide the financial support and an excellent research environment, also for excellent advices.

To Dr. Frank Edlich, who has play the key role in the execution of the “FKBP38 Project”, for all the preparative support, for his help in the design and execution of the different experiments, and for very productive discussions.

To Franziska Jarczowski for her decisive contribution to the cloning, expression and purification of the FKBP domain.

To Beate Rappsilber and Melanie Kirchner for doing most of the work in the preparation of several FKBP38 and CaM samples.

To Dr. Güther Jahreis, who provided the peptides for the NMR experiments.

To the AK Stubs, especially Beatrice Epler, Dr. Piotr Neumann, and Dr. Christoph Parthier, for their valuable contribution to the crystallographic structural determination of the FKBP domain.

To Monica Seidel, for valuable help in the work with the spectrometer and for been a very good friend at work.

To Lucia Moresanu-Lücke and Carmen Mrestani, who shared a lot of nice time with us, forming a small “NMR group”.

To Katja Heydenreich for continuing this project, providing some new results that in fact contribute to this work.

To the rest of the collective of the Max-Planck Research Unit for Enzymology of Protein Folding, for sharing some moments at seminars, parties, etc, and for any help provided.

This work is dedicated to my wife and to my parents.

8.3. Curriculum vitae

Surname Maestre Martínez

Name Mitcheell

Date of birth 29.04.1974

Place of birth Havana, Cuba

Citizenship Cuban

Legal status Married

School

1980-1986 Primary School “Jorge Agostini”, Havana, Cuba

1986-1987 High School “Raul Gomez”, Havana, Cuba

1987-1989 High School “Mariana Grajales”, Havana, Cuba

1989-1992 Senior High School “IPVCE V.I. Lenin”, Havana, Cuba

Studies

1992-1997 Chemistry studies at the Faculty of Chemistry, University of Havana

1997 Diploma in Chemistry at the Department of Physical Chemistry, Faculty of Chemistry, University of Havana. Title: “Conformational study of oligomers of the antigenic determinant of *Haemophilus influenzae* type b by NMR and Molecular Dynamics”

1997- 2002 Graduate Student at the Department of Physical Chemistry, Faculty of Chemistry, University of Havana

2002- 2003 PhD Student at the Institute for Biophysical Chemistry, University of Frankfurt

2003- 2007 PhD Student at the Max-Planck Research Unit for Enzymology of Protein Folding, Halle, Advisor: P.D. Dr. C. Lücke
Dissertation under advice from: P.D. Dr. C. Lücke
Topic: NMR structural characterization of FKBP38 and its interactions with calmodulin

Halle/Saale, im August 2007

Eidesstattliche Erklärung

Hiermit erkläre ich, dass die vorliegende Arbeit von mir selbständig und nur unter Verwendung der angegebenen Hilfsmittel angefertigt wurde. Ich versichere weiterhin, dass alle wörtlich oder inhaltlich entnommenen Stellen als solch gekennzeichnet sind.

Diese Arbeit wurde bisher an keine andere Universität vorgelegt.
